ICALP

Principle

Developing a **quantitative** notion of **regularity** which extends in many ways the standard notion of regularity:

- **presentations**: automata (det/non-det), algebra, logic, regular expressions
- **closure**: union, intersection, projection, complementation
- **decidability**: emptiness

Key idea. Consider mappings $f, g : \mathbb{A}^* \rightarrow \omega + 1$ modulo an equivalence which preserves the existence of bounds:

$$f \approx g \quad : \quad \forall X \subseteq \mathbb{A}^*. \quad f|_X \text{ is bounded} \quad \text{iff} \quad g|_X \text{ is bounded}$$

Origin and motivations

A model with many “good” properties is worth being studied.

Our automata are extensions of **distance automata** [Hashiguchi81], **desert automata** [Kirsten04], and **nested distance desert automata** [Kirsten05].

Those models were introduced for deciding language theoretic questions: the **finite power problem**, the **finite substitution problem**, the **star-height problem**.

All problems can be solved by a reduction to a problem of **existence of bound** for the above automata.

In [Bojanczyk, C.06], B-automata (similar) were introduced together with a **dual variant**, S-automata.

Outline

- 1 Cost functions
- 2 Automata for cost functions
- 3 Algebraic framework
- 4 Conclusion

- 1 Cost functions
- 2 Automata for cost functions
- 3 Algebraic framework
- 4 Conclusion

Cost functions

Definition

Consider mappings $f, g : E \rightarrow \omega + 1$ ($E = \mathbb{A}^*$ in this work), define

$f \preceq g$ if $\forall X \subseteq \mathbb{A}^*. g|_X$ is bounded implies $f|_X$ is bounded

$f \approx g$ if $f \preceq g$ and $g \preceq f$

A **cost function** (over E) is an equivalence class for \approx .

Cost functions

Definition

Consider mappings $f, g : E \rightarrow \omega + 1$ ($E = \mathbb{A}^*$ in this work), define

$f \preceq g$ if $\forall X \subseteq \mathbb{A}^*. g|_X$ is bounded implies $f|_X$ is bounded

$f \approx g$ if $f \preceq g$ and $g \preceq f$

A **cost function** (over E) is an equivalence class for \approx .

Example

- $0 \preceq |\cdot|_a \preceq |\cdot|$
- $|\cdot|_a$ and $|\cdot|_b$ are incomparable
- $|\cdot|_a + |\cdot|_b \approx \max(|\cdot|_a, |\cdot|_b)$ (more generally, $\max \approx +$)

Cost functions

Definition

Consider mappings $f, g : E \rightarrow \omega + 1$ ($E = \mathbb{A}^*$ in this work), define

$f \preceq g$ if $\forall X \subseteq \mathbb{A}^*. g|_X$ is bounded implies $f|_X$ is bounded

$f \approx g$ if $f \preceq g$ and $g \preceq f$

A **cost function** (over E) is an equivalence class for \approx .

Remark (Cost functions extend languages)

For $L \subseteq E$ (a language), define $\chi_L : E \rightarrow \omega + 1$ by:

$$\chi_L(x) = \begin{cases} 0 & \text{if } x \in L \\ \omega & \text{otherwise} \end{cases}$$

Then for all $K, L \subseteq E$, $\chi_K \preceq \chi_L$ iff $L \subseteq K$.

- 1 Cost functions
- 2 Automata for cost functions**
- 3 Algebraic framework
- 4 Conclusion

Computing the cost of a sequence

Let Γ be a finite set of **counters**.

Semantics: counters have initial value 0, and one can perform on them:

- ϵ , which does nothing,
- i which **increments** the counter by one,
- r which **resets** the counter (to 0), and;
- c which **checks** (i.e., observes/tests) the counter value.

Given a sequence $u \in (\{\epsilon, i, r, c\}^\Gamma)^*$, $C(u)$ is the set of values of counters when checked.

Cost automata

Definition

A **cost automaton** $\mathcal{A} = (Q, \mathbb{A}, I, F, \Gamma, \Delta)$ has:

- a finite set Q of **states**, an **input alphabet** \mathbb{A} , a set I of **initial states**, a set F of **final states**,
- a finite set Γ of **counters**,
- a **transition relation** $\Delta \subseteq Q \times \mathbb{A} \times \{\epsilon, i, r, c\}^\Gamma \times Q$.

Runs are defined as usual. One defines:

$$[[\mathcal{A}]]_B : \mathbb{A}^* \mapsto \omega + 1$$

$$u \mapsto \inf\{\sup C(\rho) : \rho \text{ accepting run of } \mathcal{A} \text{ over } u\}$$

$$[[\mathcal{A}]]_S : \mathbb{A}^* \mapsto \omega + 1$$

$$u \mapsto \sup\{\inf C(\rho) : \rho \text{ accepting run of } \mathcal{A} \text{ over } u\}$$

Cost automata are called **B-automata** or **S-automata** accordingly.

Example of a deterministic B-automaton

$$\llbracket \mathcal{A} \rrbracket_B(u) = \inf\{\sup C(\sigma) : \sigma \text{ accepting run of } \mathcal{A} \text{ over } u\}$$

The following deterministic B-automaton counts the number of occurrences of 'a'.

$$C(\sigma) = \{1, 2, \dots, |u|_a\}$$

Example of a deterministic S-automaton

$$\llbracket \mathcal{A} \rrbracket_S(u) = \sup \{ \inf C(\sigma) : \sigma \text{ accepting run of } \mathcal{A} \text{ over } u \}$$

The following deterministic S-automaton computes the minimal distance between two b 's (ω if less than two b 's).

$$C(\sigma) = \{ \text{distances between consecutive } b\text{'s} \}$$

Example of a (non-deterministic) B-automaton

$$\llbracket \mathcal{A} \rrbracket_B(u) = \inf\{\sup C(\sigma) : \sigma \text{ accepting run of } \mathcal{A} \text{ over } u\}$$

The following B-automaton computes the minimal distance between two b 's (ω if less than two b 's).

$$C(\sigma) = \{1, 2, \dots, \text{distance between the two guessed } b\text{'s}\}$$

Link with the language case

$$\llbracket \mathcal{A} \rrbracket_B(u) = \inf\{\sup C(\sigma) : \sigma \text{ accepting run of } \mathcal{A} \text{ over } u\}$$

$$\llbracket \mathcal{A} \rrbracket_S(u) = \sup\{\inf C(\sigma) : \sigma \text{ accepting run of } \mathcal{A} \text{ over } u\}$$

Remark

If \mathcal{A} has no counters and accepts L , then $\begin{cases} \llbracket \mathcal{A} \rrbracket_B = \chi_L \\ \llbracket \mathcal{A} \rrbracket_S = \chi_{\mathbf{C}L} \end{cases}$

Closure results

Fact

Cost functions accepted by B-automata (resp. S-automata) are closed under min and max.

Cost functions accepted by B-automata (resp. S-automata) are closed under inf-projection (resp. sup-projection).

This corresponds to **union**, **intersection** and **projection** for regular languages.

Closure results

Fact

Cost functions accepted by B-automata (resp. S-automata) are closed under min and max.

Cost functions accepted by B-automata (resp. S-automata) are closed under inf-projection (resp. sup-projection).

This corresponds to **union**, **intersection** and **projection** for regular languages.

Theorem (**duality**, [here] and [Bojanczyk&C.06])

*A cost function is accepted by a B-automaton iff it is accepted by an S-automaton (**modulo** \approx). The equivalences are elementary. We call such cost functions **regular**.*

This corresponds to the **complementation** of regular languages.

This corresponds to the **complementation** of regular languages.

Proof: go to the algebraic world...

Key decidability result

Theorem

The relation \preceq is decidable over regular cost functions.

This corresponds to the decidability of the **inclusion** for regular languages.

Corollary (boundedness, limitedness)

One can decide whether a regular cost function is bounded.

Proof. f is bounded iff $f \preceq 0$.

Stabilization monoids (following I. Simon)

Definition

A **stabilization monoid** $\langle M, \cdot, \leq, \sharp \rangle$ is an ordered monoid $\langle M, \cdot, \leq \rangle$ together with a **stabilization operator** $\sharp : E(M) \rightarrow E(M)$ ($E(M)$ are the idempotents of M), such that:

consistency if $a \cdot b, b \cdot a \in E(M)$, then $(a \cdot b)^\sharp = a \cdot (b \cdot a)^\sharp \cdot b$,

order for $e, f \in E(M)$, $e \leq f$ implies $e^\sharp \leq f^\sharp \leq f$, and;

neutral $1^\sharp = 1$.

Intuitively, e^\sharp represents the value of e when iterated a **lot of time**.

If $e^\sharp = e$, one does not care about the number of occurrences of e .

If $e^\sharp < e$, the stabilization monoid 'counts' the iterations of e .

Example of a stabilization semigroup 'counting a 's'

$$\begin{array}{|l} b = b \cdot b = b^\# (= 1) \end{array}$$

$$\begin{array}{|l} a = a \cdot a = b \cdot a = a \cdot b (\neq a^\#) \end{array}$$

$$\begin{array}{|l} \perp = \star \cdot \perp = \perp \cdot \star = a^\# = \perp^\# \end{array}$$

Example of a stabilization semigroup 'counting a 's'

One classifies the words over M^* (with $M = \{a, b, \perp\}$)

$$b = b \cdot b = b^\# (= 1)$$

words in b^*

$$a = a \cdot a = b \cdot a = a \cdot b (\neq a^\#)$$

words in $(b^*a)^+b^*$ with **few** a 's

$$\perp = \star \cdot \perp = \perp \cdot \star = a^\# = \perp^\#$$

words containing \perp , or a **lot of** a 's

Example of a stabilization semigroup 'counting a 's'

One classifies the words over M^* (with $M = \{a, b, \perp\}$)
 Formally, $\rho : M^* \rightarrow \omega \rightarrow M$ (non-decreasing)

$$\left\| \begin{array}{l} b = b \cdot b = b^\# (= 1) \\ \text{words in } b^* \\ \rho(u)(n) = b \text{ if } u \in b^* \end{array} \right.$$

$$\left\| \begin{array}{l} a = a \cdot a = b \cdot a = a \cdot b (\neq a^\#) \\ \text{words in } (b^*a)^+b^* \text{ with few } a\text{'s} \\ \rho(u)(n) = b \text{ if } |u|_\perp = 0 \text{ and } 1 \leq |u|_a < n \end{array} \right.$$

$$\left\| \begin{array}{l} \perp = \star \cdot \perp = \perp \cdot \star = a^\# = \perp^\# \\ \text{words containing } \perp, \text{ or a lot of } a\text{'s} \\ \rho(u)(n) = \perp \text{ if } |u|_\perp \geq 1 \text{ or } n \leq |u|_a \end{array} \right.$$

Example of a stabilization semigroup 'counting a 's'

One classifies the words over M^* (with $M = \{a, b, \perp\}$)
 Formally, $\rho : M^* \rightarrow \omega \rightarrow M$ (non-decreasing)

$$\left\| \begin{array}{l} b = b \cdot b = b^\# (= 1) \\ \text{words in } b^* \\ \rho(u)(n) = b \text{ if } u \in b^* \end{array} \right.$$

$$\left\| \begin{array}{l} a = a \cdot a = b \cdot a = a \cdot b (\neq a^\#) \\ \text{words in } (b^*a)^+b^* \text{ with few } a\text{'s} \\ \rho(u)(n) = b \text{ if } |u|_\perp = 0 \text{ and } 1 \leq |u|_a < n \end{array} \right.$$

$$\left\| \begin{array}{l} \perp = \star \cdot \perp = \perp \cdot \star = a^\# = \perp^\# \\ \text{words containing } \perp, \text{ or a lot of } a\text{'s} \\ \rho(u)(n) = \perp \text{ if } |u|_\perp \geq 1 \text{ or } n \leq |u|_a \end{array} \right.$$

ρ is an example of a mapping **compatible with** $\langle M, \leq, \cdot, \# \rangle$.

Semantics of stabilization monoids

Theorem (Existence and unicity of semantics)

Every finite stabilization monoid admits a compatible mapping. Furthermore, it is unique up to \sim (a variant of \approx).

Recognizability

Let $h : \mathbb{A} \rightarrow M$ (extended as a morphism from \mathbb{A}^* to M^*), and I an ideal of $\langle M, \leq \rangle$. Define:

$$\text{for all } u \in \mathbb{A}^*, \quad f(u) = \sup\{n : \rho(h(u)) \in I\} .$$

Then f is said **recognized by M, h, I** .

Theorem

A cost function is regular iff it is recognizable by a finite stabilization monoid.

Example: recall that $\rho(u)(n) = \perp$ iff $|u|_{\perp} \geq 1$ or $n \leq |u|_a$.
Set $f(a) = a$, $h(b) = b$, $I = \{\perp\}$. Then M, h, I recognizes $|\cdot|_a$.

- 4 Conclusion**

Conclusion

Content of the paper:

- Cost functions extending languages
- Automata (B- and S-), duality, closure properties, decidability
- History-determinism
- Stabilization monoid/recognizability/equivalence with regularity

Related results, ongoing work, and possible extensions:

- Extension to infinite words, finite trees (with C. Löding), and infinite trees (**open**)
- Algebraic characterization of families of regular cost functions (with S. Lombardy and D. Kuperberg)
- Equivalence with a variant of monadic second-order logic
