

# Improved bounds for the randomized decision tree complexity of recursive majority\*

Frédéric Magniez<sup>†</sup>    Ashwin Nayak<sup>‡</sup>    Miklos Santha<sup>§</sup>    David Xiao<sup>¶</sup>

## Abstract

We consider the randomized decision tree complexity of the recursive 3-majority function. For evaluating a height  $h$  formulae, we prove a lower bound for the  $\delta$ -two-sided-error randomized decision tree complexity of  $(1 - 2\delta)(5/2)^h$ , improving the lower bound of  $(1 - 2\delta)(7/3)^h$  given by Jayram *et al.* (STOC '03). We also state a conjecture which would further improve the lower bound to  $(1 - 2\delta)2.54355^h$ .

Second, we improve the upper bound by giving a new zero-error randomized decision tree algorithm that has complexity at most  $(1.007) \cdot 2.64946^h$ , improving on the previous best known algorithm, which achieved  $(1.004) \cdot 2.65622^h$ .

Our lower bound follows from a better analysis of the base case of the recursion of Jayram *et al.*. Our algorithm uses a novel “interleaving” of two recursive algorithms.

# 1 Introduction

Decision trees form a simple model for computing boolean functions by successively reading the input bits until the value of the function can be determined with certainty. The cost associated with this computation is the number of input bits queried, all other computations are free. Formally, a *deterministic decision tree algorithm*  $A$  on  $n$  variables is a binary tree in which each internal node is labeled with an input variable  $x_i$ , for some  $1 \leq i \leq n$ . The leaves of the tree are labeled by one of the output values 0 or 1, and for every internal node, one of the outgoing edges is labeled by 0 and the other by the 1. For every input  $x = x_1 \dots x_n$ , there is a unique path in the tree leading from the root to one of the leaves, which follows, at every node, the outgoing edge whose label coincides with the value of the input bit corresponding to the label of the node. The value of the algorithm  $A$  on input  $x$ , denoted by  $A(x)$ , is the label of the leaf on this unique path. The algorithm  $A$  *computes* a boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  if for every input  $x$ , we have  $A(x) = f(x)$ .

We define the *cost*  $C(A, x)$  of a deterministic decision tree algorithm  $A$  on input  $x$  as the number of input bits queried by  $A$  on  $x$ . Let  $\mathcal{P}_f$  be the set of all deterministic decision tree algorithms which compute  $f$ . The *deterministic complexity* of  $f$  is

$$D(f) = \min_{A \in \mathcal{P}_f} \max_{x \in \{0,1\}^n} C(A, x).$$

Since every function can be evaluated after reading all the input variables,  $D(f) \leq n$ . In an extension of the deterministic model, we can also permit randomization in the computation.

A *randomized decision tree algorithm*  $A$  on  $n$  variables is a distribution over all deterministic decision tree algorithms on  $n$  variables. Given an input  $x$ , the algorithm first samples a deterministic tree  $B \in_R A$ , then evaluates  $B(x)$ . The error probability of  $A$  in computing  $f$  is given by  $\max_{x \in \{0,1\}^n} \Pr_{B \in_R A}[B(x) \neq f(x)]$ . The *cost* of a randomized algorithm  $A$  on input  $x$ , denoted also by  $C(A, x)$ , is the expected number of input bits queried by  $A$  on  $x$ . Let  $\mathcal{P}_f^\delta$  be the set of randomized decision tree algorithms computing  $f$  with error at most  $\delta$ . The two-sided bounded error *randomized complexity* of  $f$  with error  $\delta \in [0, 1/2)$  is

$$R^\delta(f) = \min_{A \in \mathcal{P}_f^\delta} \max_{x \in \{0,1\}^n} C(A, x).$$

We write  $R(f)$  for  $R^0(f)$ . By definition, for all  $0 \leq \delta \leq 1/2$ , it holds that  $R^\delta(f) \leq R(f) \leq D(f)$ , and it is also known [1, 2, 10] that  $D(f) \leq R(f)^2$ , and that for all constant  $\delta \in (0, 1/2)$ ,  $D(f) < O(R^\delta(f)^3)$  [7].

Considerable attention in the literature has been given to the randomized complexity of functions computable by read-once formulae, that is by boolean formulae in which every input variable appears only once. For a large class of well balanced formulae with NAND gates the exact randomized complexity is known. In particular, let  $\text{NAND}_h$  denote the *complete* binary tree of height  $h$  with NAND gates, where the inputs are at the  $n = 2^h$  leaves. Snir [9] has shown that  $R(\text{NAND}_h) = O(n^c)$  where  $c = \log_2\left(\frac{1+\sqrt{33}}{4}\right) \approx 0.753$ . A matching  $\Omega(n^c)$  lower bound was obtained by Saks and Wigderson [8]. Since  $D(\text{NAND}_h) = 2^h = n$  this implies that  $R(\text{NAND}_h) = \Theta(D(\text{NAND}_h)^c)$ , and Saks and Wigderson have also conjectured that this is the largest gap between deterministic and randomized complexity.

**Conjecture 1.1** (Saks and Wigderson [8]). *For every boolean function  $f$  and constant  $\delta \in [0, 1/2)$ ,  $R^\delta(f) = \Omega(D(f)^c)$ .*

For the randomized complexity of read-once threshold formula of depth  $d$ , Heiman, Newman, and Wigderson [4] proved a lower bound of  $\Omega(n/2^d)$ . Heiman and Wigderson [3] proved that the randomized complexity of every read-once formula  $f$  is at least  $\Omega(D(f)^{0.51})$ .

After these initial successes one would have hoped that the simple model of decision tree algorithms might shed more light on the power of randomness. But surprisingly, we know the exact randomized complexity of very few boolean functions. In particular, the randomized complexity of the recursive 3-majority function ( $\text{3-MAJ}_h$ ) is still open. This function, proposed by Boppana, was one of the earliest example where randomized algorithms were found to be more powerful than deterministic decision trees [8]. It is a read-once formula

on  $3^h$  variable given by the complete ternary tree of height  $h$  whose internal vertices are majority gates. The deterministic decision tree complexity of  $3\text{-MAJ}_h$  is easily seen to be  $3^h$ . There is a naive randomized recursive algorithm for  $3\text{-MAJ}_h$  that picks two random children of the root and recursively evaluates them, then evaluates the third child iff the value is not determined by the previously evaluated two children. It is easy to check that this has randomized complexity  $(8/3)^h$ . It was already observed by Saks and Wigderson [8] that this algorithm is not optimal. In spite of some similarities with the  $\text{NAND}_h$  function, no progress was reported on the randomized complexity of  $3\text{-MAJ}$  for 17 years, beyond the bounds derived for arbitrary boolean functions [4, 3]. In 2003, Jayram, Kumar, and Sivakumar [5] proposed an explicit randomized algorithm that achieves complexity  $(1.004) \cdot 2.65622^h$ , and beats the naive recursion. (Note, however, that the analysis in [5, Appendix B] is incorrect.) More importantly, they also prove a  $(1 - 2\delta)(7/3)^h$  lower bound for the  $\delta$ -error randomized decision tree complexity of  $3\text{-MAJ}_h$ . In doing so, they introduce a powerful combinatorial technique for proving decision tree lower bounds.

In this paper, we considerably improve the lower bound obtained in [5], by proving that  $R^\delta(3\text{-MAJ}_h) \geq (1 - 2\delta)(5/2)^h$ . In the appendix we also state a conjecture which would further raise the lower bound to  $(1 - 2\delta)2.54355^h$ . We also improve the upper bound by giving a new zero-error randomized decision tree algorithm that has complexity at most  $(1.007)2.64946^h$ .

**Theorem 1.2.** *For all  $\delta \in [0, 1/2]$ , we have  $(1 - 2\delta)(5/2)^h \leq R^\delta(3\text{-MAJ}_h) \leq (1.007)2.64946^h$ .*

**New lower bound.** For the lower bound they give, Jayram *et al.* consider a complexity measure related to the distributional complexity of  $3\text{-MAJ}_h$  with respect to a specific hard distribution (cf. Section 2.3). The focus of the proof is a relationship between the complexity of evaluating formulae of height  $h$  to that of evaluating formulae of height  $h - 1$ . They derive a sophisticated recurrence relation between these two quantities, that finally implies that  $R^\delta(3\text{-MAJ}_h) \geq (1 - 2\delta)(2 + q)^h$ , where  $(1 - 2\delta)q^h$  is a lower bound on the probability  $p_h^\delta$  that a randomized algorithm with error at most  $\delta$  queries the “absolute minority” on inputs drawn from the hard distribution. (The absolute minority is the unique leaf in the recursive majority tree over a hard instance such that the path leading from this leaf to the root has alternating values.) Jayram *et al.* observe that any randomized decision tree with error at most  $\delta$  queries at least one variable with probability at least  $1 - 2\delta$ . This variable has probability  $3^{-h}$  of being the absolute minority, so  $q \geq 1/3$ , and the above lower bound follows.

We obtain the new lower bound by proving that  $p_h^\delta \geq (1 - 2\delta)2^{-h}$ , i.e.,  $q \geq 1/2$ , which immediately implies the improved lower bound for  $R^\delta(3\text{-MAJ}_h)$ . The obvious method for deriving a such a lower bound is to consider the queries that an algorithm makes beyond the first. This approach quickly runs aground, as it requires an analysis of the hard distribution conditioned upon values of a subset of the variables, which seems intractable. Instead, we examine the relationship between  $p_h^\delta$  and  $p_{h-1}^\delta$ , by embedding a height  $h - 1$  instance into one with height  $h$  and using an algorithm for the latter. Unlike the embedding used by Jayram *et al.* (which runs into the same difficulty as the obvious approach), the new embedding reduces the analysis to understanding the behavior of decision trees on 3 variables, which can be done by hand. In the appendix, we give a conjecture that would further improve the lower bound by relating  $p_h^\delta$  to  $p_{h-2}^\delta$ , although a complete analysis seems out of reach as it involves examining all possible decision trees on 9 variables.

**New algorithm.** The new algorithm we design arises from a more nuanced application of the intuition behind the two known algorithms. One way of viewing the naive recursive algorithm is that it strives to avoid evaluating the minority child of a node. A more fruitful view is that it attempts to make an informed opinion on the value of a node by computing the value of a random child. The algorithm described in the appendix of [5] can also be viewed in this light, and performs notably better, achieving complexity  $(1.004) \cdot 2.65622^h$ .

The algorithms mentioned above are examples of *depth- $k$*  recursive algorithms for  $3\text{-MAJ}_h$ , for  $k = 1, 2$ , respectively. A *depth- $k$*  recursive algorithm is a collection of subroutines, where each subroutine evaluates a node (possibly using information about other previously evaluated nodes), satisfying the following constraint: when a subroutine evaluates a node  $v$ , it is only allowed to call other subroutines to evaluate children of  $v$  at depth at most  $k$ , but is not allowed to call subroutines or otherwise evaluate children that are deeper than

$k$ . (Our notion of depth-1 is identical to the terminology “directional” that appears in the literature. In particular, the naive recursive algorithm is a directional algorithm.)

The algorithm we present is an improved depth-two recursive algorithm. It recursively computes the values of two grandchildren from distinct children, to form an opinion on the values of the corresponding children. The opinion guides the remaining computation in a natural manner, i.e., if the opinion indicates that the two children are likely to be majority children, we evaluate the children in sequence to confirm the opinion. At any point, if the value of a child refutes it, we update our opinion, and modify our future computations accordingly. A key innovation is the use of an algorithm optimized to compute the value of a partially evaluated formula. In our analysis, we recognize when incorrect opinions are formed, and take advantage of the fact that this happens with smaller probability.

We do not believe that the algorithm we present here is optimal. Indeed, we conjecture that even better algorithms exist that follow the same high level intuition applied for depth- $k$  recursion for  $k > 2$ . However, it seems new insights are required to analyze the performance of deeper recursions, as the formulas describing their complexity become unmanageable for  $k > 2$ .

**Organization.** The rest of the article is organized as follows. We prepare the background for our main results in [Section 2](#). In [Section 3](#) we prove the new lower bound for 3-MAJ. We conjecture a better lower bound in [Section A](#) in the appendix. The new algorithm for the problem is described and analyzed in [Section 4](#). A formal description of the algorithm occurs in [Section B](#) in the appendix.

## 2 Preliminaries

We write  $u \in_{\mathbb{R}} D$  to state that  $u$  is sampled from the distribution  $D$ . If  $X$  is a finite set, we identify  $X$  with the uniform distribution over  $X$ , and so, for instance,  $u \in_{\mathbb{R}} X$  denotes a uniform element of  $X$ .

### 2.1 Distributional complexity

A variant of the randomized complexity we use is *distributional* complexity. Let  $\mathcal{D}_n$  be the set of distributions over  $\{0, 1\}^n$ . The *cost*  $C(A, D)$  of a randomized decision tree algorithm  $A$  on  $n$  variables with respect to a distribution  $D \in \mathcal{D}_n$  is the expected number of bits queried by  $A$  when  $x$  is sampled from  $D$  and over the random coins of  $A$ . The distributional complexity of a function  $f$  on  $n$  variables for  $\delta$  two-sided error is

$$\Delta^\delta(f) = \max_{D \in \mathcal{D}_n} \min_{A \in \mathcal{P}_f^\delta} C(A, D).$$

The following observation is a well established route to proving lower bounds on worst case complexity.

**Fact 2.1.**  $R^\delta(f) \geq \Delta^\delta(f)$ .

### 2.2 The 3-MAJ $_h$ function and the hard distribution

Let MAJ( $x$ ) denote the boolean majority function of its input bits. The ternary majority function 3-MAJ $_h$  is defined recursively on  $n = 3^h$  variables, for every  $h \geq 0$ . For  $h = 0$  it is the identity function. For  $h > 0$ ,

$$\begin{aligned} & 3\text{-MAJ}_h(x_1 \dots x_{3^h}) \\ &= \text{MAJ}(3\text{-MAJ}_{h-1}(x_1 \dots x_{3^{h-1}}), 3\text{-MAJ}_{h-1}(x_{3^{h-1}+1} \dots x_{2 \cdot 3^{h-1}}), 3\text{-MAJ}_{h-1}(x_{2 \cdot 3^{h-1}+1} \dots x_{3^h})). \end{aligned}$$

If the height  $h$  of the formula is clear from the context, we drop the subscript from 3-MAJ $_h$ .

For every node  $v$  in  $T_h$  different from the root, let  $P(v)$  denote the parent of  $v$ . We say that  $v$  and  $w$  are siblings if  $P(v) = P(w)$ . For any node  $v$  in  $T_h$ , let  $Z(v)$  denote the set of variables associated with the leaves in the subtree rooted at  $v$ . We say that a node  $v$  is at depth  $d$  in  $T_h$  if the distance between  $v$  and the root is  $d$ . The root is therefore at depth 0, and the leaves are at depth  $h$ .

We now define recursively, for every  $h \geq 0$ , the set  $\mathcal{H}_h$  of *hard inputs* of height  $h$ , (or equivalently, of length  $3^h$ ). The hard inputs consist of instances for which at each node  $v$  in the ternary tree, one child of

$v$  has value different from the value of  $v$ . For  $b \in \{0, 1\}$ , let  $\mathcal{H}_h^b = \{x \in \mathcal{H}_h : 3\text{-MAJ}_h(x) = b\}$ . The *hard distribution* on inputs of height  $h$  is defined to be the uniform distribution over  $\mathcal{H}_h$ .

For an  $x \in \mathcal{H}_h$ , the *minority path*  $M(x)$  is the path, starting at the root, obtained by following the child whose value disagrees with its parent. For  $0 \leq d \leq h$ , the node of  $M(x)$  at depth  $d$  is called the depth  $d$  minority node, and is denoted by  $M(x)_d$ . We call the leaf  $M(x)_h$  of the minority path the *absolute minority* of  $x$ , and denote it by  $m(x)$ .

### 2.3 The Jayram-Kumar-Sivakumar lower bound

For a deterministic decision tree algorithm  $B$  computing  $3\text{-MAJ}_h$ , let  $L_B(x)$  denote the set of variables queried by  $B$  on input  $x$ . Recall that  $\mathcal{P}_{3\text{-MAJ}_h}^\delta$  is the set of all randomized decision tree algorithms that compute  $3\text{-MAJ}_h$  with two-sided error at most  $\delta$ . Jayram *et al.* define the function  $I^\delta(h, d)$ , for  $d \leq h$ , as follows:

$$I^\delta(h, d) = \min_{A \in \mathcal{P}_{3\text{-MAJ}_h}^\delta} \mathbb{E}_{x \in \mathcal{R}\mathcal{H}_h, B \in \mathcal{R}A} [|Z(M(x)_d) \cap L_B(x)|].$$

The expectation is taken over the choice of  $B \in \mathcal{R}A$  and the choice of input  $x$ . In words, it is the minimum over algorithms computing  $3\text{-MAJ}_h$ , of the expected number of queries below the  $d$ th level minority node, over inputs from the hard distribution. Note that  $I^\delta(h, 0) = \min_{A \in \mathcal{P}_{3\text{-MAJ}_h}^\delta} C(A, \mathcal{H}_h)$ , and therefore by [Fact 2.1](#):

$$R^\delta(3\text{-MAJ}_h) \geq I^\delta(h, 0). \quad (1)$$

Observe also that  $I^\delta(h, h)$  is the minimal probability that a  $\delta$ -error algorithm  $A$  queries the absolute minority of a random hard  $x$  of height  $h$ . We denote  $I^\delta(h, h)$  by  $p_h^\delta$ .

Jayram *et al.* prove a recursive lower bound for  $I^\delta(h, d)$  using information theoretic arguments. A more elementary proof can be found in Ref. [\[6\]](#).

**Theorem 2.2** (Jayram, Kumar, Sivakumar [\[5\]](#)). *For all  $0 \leq d < h$ , it holds that*

$$I^\delta(h, d) \geq I^\delta(h, d+1) + 2I^\delta(h-1, d).$$

A simple computation using their recursion gives  $I(h, 0) \geq \sum_{i=0}^h \binom{h}{i} 2^{h-i} p_i^\delta$ . Putting this together with [Equation 1](#) we get the following corollary:

**Corollary 2.3.** *Let  $q, a > 0$  such that  $p_i^\delta \geq a \cdot q^i$  for all  $i \in \{0, 1, 2, \dots, h\}$ . Then  $R^\delta(3\text{-MAJ}_h) \geq a(2+q)^h$ .*

As mentioned in [Section 1](#), Jayram *et al.* obtain the  $(1-2\delta)(7/3)^h$  lower bound this corollary by observing that  $p_h^\delta \geq (1-2\delta)(1/3)^h$ .

## 3 Improved Lower Bound

**Theorem 3.1.** *For every error  $\delta > 0$  and height  $h \geq 0$ , we have  $p_h^\delta \geq (1-2\delta)2^{-h}$ .*

*Proof.* We prove this theorem by induction. Clearly,  $p_0^\delta \geq 1-2\delta$ , therefore, it suffices to show that  $2p_h^\delta \geq p_{h-1}^\delta$  for  $h \geq 1$ . We do so by reduction as follows: let  $A$  be a randomized algorithm that achieves the minimal probability  $p_h^\delta$  for height  $h$  formulae. We construct a randomized algorithm  $A'$  for height  $h-1$  formulae such that the probability that  $A'$  errs is at most  $\delta$ , and  $A'$  queries the absolute minority with probability at most  $2p_h^\delta$ . Since  $p_{h-1}^\delta$  is the minimum probability of querying the absolute minority over all randomized algorithms on inputs of height  $h-1$  with error at most  $\delta$ , this implies that  $2p_h^\delta \geq p_{h-1}^\delta$ .

We now specify the reduction. For the sake of simplicity, we will omit the error  $\delta$  in the notation. We use the following definition:

**Definition 3.2** (One level encoding scheme). A *one level encoding scheme* is a map  $\psi$  which is a bijection for every  $h \geq 1$ , mapping  $\mathcal{H}_{h-1} \times \{1, 2, 3\}^{3^{h-1}}$  to  $\mathcal{H}_h$ , such that for every  $(y, r)$  in its domain with  $y \in \mathcal{H}_{h-1}$ ,  $3\text{-MAJ}_{h-1}(y) = 3\text{-MAJ}_h(\psi(y, r))$ .

Let  $c : \{0, 1\} \times \{1, 2, 3\} \rightarrow \mathcal{H}_1$  be a function which for every  $(b, s) \in \{0, 1\} \times \{1, 2, 3\}$  satisfies  $b = \text{MAJ}(c(b, s))$ . The one level encoding scheme  $\psi$  induced by  $c$  is defined for each  $h \geq 1$  as follows:  $\psi(y, r) = x \in \mathcal{H}_h$  such that for all  $1 \leq i \leq 3^{h-1}$

$$(x_{3i-2}, x_{3i-1}, x_{3i}) = c(y_i, r_i).$$

To define  $A'$ , we use the one level encoding scheme  $\psi$  induced by the function  $c : \{0, 1\} \times \{1, 2, 3\} \rightarrow \mathcal{H}_1$  defined as

$$c(y, r) = \begin{cases} y01 & \text{if } r = 1, \\ 1y0 & \text{if } r = 2, \\ 01y & \text{if } r = 3. \end{cases} \quad \text{and} \quad (2)$$

On input  $y$ , by definition  $A'$  picks a uniformly random string  $r = r_1 \dots r_{3^{h-1}}$  from  $\{1, 2, 3\}^{3^{h-1}}$ , and runs  $A$  on  $x = \psi(y, r)$ . Observe that  $A'$  has error at most  $\delta$  since  $3\text{-MAJ}_{h-1}(y) = 3\text{-MAJ}_h(\psi(y, r))$  for all  $r$ , and  $A$  has error at most  $\delta$ . We claim now:

$$2 \Pr_{A, x \in_{\mathbb{R}} \mathcal{H}_h} [A(x) \text{ queries } x_{m(x)}] \geq \Pr_{A', (y, r) \in_{\mathbb{R}} \mathcal{H}'_h} [A'(y, r) \text{ queries } y_{m(y)}], \quad (3)$$

where  $\mathcal{H}'_h$  is the uniform distribution over  $\mathcal{H}_{h-1} \times \{1, 2, 3\}^{3^{h-1}}$ .

We prove this inequality by taking an appropriate partition of the probabilistic space of hard inputs  $\mathcal{H}_h$ , and prove Equation 3 separately, on each set in the partition. For  $h = 1$ , the two classes of the partition are  $\mathcal{H}_1^0$  and  $\mathcal{H}_1^1$ . For  $h > 1$ , the partition consists of the equivalence classes of the relation  $\sim$  defined by  $x \sim x'$  if  $x_i = x'_i$  for all  $i$  such  $P(i) \neq P(m(x))$  in the tree  $T$ .

Because  $\psi$  is a bijection, observe that this also induces a partition of  $(y, r)$ , where  $(y, r) \sim (y', r')$  iff  $\psi(y, r) \sim \psi(y', r')$ . Also observe that every equivalence class contains three elements. Let  $S$  be an equivalence class of  $\sim$ . Then Equation 3 follows from the following stronger statement: for every  $S$ , and for all  $B$  in the support of  $A$ , it holds that

$$2 \Pr_{x \in_{\mathbb{R}} \mathcal{H}_h} [B(x) \text{ queries } x_{m(x)} \mid x \in S] \geq \Pr_{(y, r) \in_{\mathbb{R}} \mathcal{H}'_h} [B'(y, r) \text{ queries } y_{m(y)} \mid \psi(y, r) \in S]. \quad (4)$$

where  $B'$  is the algorithm that computes  $x = \psi(y, r)$  and then evaluates  $B(x)$ .

The same proof applies to all sets  $S$ , but to simplify the notation, we consider a set  $S$  that satisfies the following: for  $x \in S$ , we have  $m(x) \in \{1, 2, 3\}$  and that  $x_{m(x)} = 1$ . Observe that for each  $j > 3$ , the  $j$ th bits of all three elements in  $S$  coincide. Therefore, the restriction of  $B$  to the variables  $(x_1, x_2, x_3)$ , when looking only at the three inputs in  $S$ , is a well-defined decision tree on three variables. We call this restriction  $B_1$ , and formally it is defined as follows: for each query  $x_j$  made by  $B$  for  $j > 3$ ,  $B_1$  simply uses the value of  $x_j$  that is shared by all  $x \in S$  and that we hard-wire into  $B_1$ ; for each query  $x_j$  made by  $B$  where  $j \in \{1, 2, 3\}$ ,  $B_1$  actually queries  $x_j$ . Note that the restriction  $B_1$  does not necessarily compute  $3\text{-MAJ}_1(x_1x_2x_3)$ , for two reasons. Firstly,  $B_1$  is derived from  $B$ , which may err on particular inputs. But even if  $B(x)$  correctly computes  $3\text{-MAJ}_h(x)$ , it might happen that  $B$  never queries any of  $x_1, x_2, x_3$ , or it might query one and never query a second one, etc.

For any  $x \in S$ , recall that we write  $(y, r) = \psi^{-1}(x)$ . It holds for our choice of  $S$  that  $m(y) = 1$  because we assumed  $m(x) \in \{1, 2, 3\}$  and also  $y_1 = y_{m(y)} = 0$  because we assumed  $x_{m(x)} = 1$ .

Observe that, for inputs  $x \in S$ ,  $B$  queries  $x_{m(x)}$  iff  $B_1$  queries the minority among  $x_1, x_2, x_3$ . Also,  $B'(y, r)$  queries  $y_{m(y)}$  iff  $B_1(\psi(0, r_1))$  queries  $x_{r_1}$  (cf. Equation 2). Furthermore, the distribution of  $x_1x_2x_3$  when  $x \in_{\mathbb{R}} S$  is uniform over  $\mathcal{H}_1^0$ . Similarly, the distribution of  $r_1$  over uniform  $(y, r)$  conditioned on  $\psi(y, r) \in S$  is identical to that of  $(0, r_1) = \psi^{-1}(x_1x_2x_3)$  for  $x_1x_2x_3 \in_{\mathbb{R}} \mathcal{H}_1^0$ . Thus Equation 4 is equivalent to:

$$2 \Pr_{x \in_{\mathbb{R}} \mathcal{H}_1^0} [B_1(x) \text{ queries } x_{m(x)}] \geq \Pr_{x \in_{\mathbb{R}} \mathcal{H}_1^0} [B_1(x) \text{ queries } x_{r_1} \text{ where } (0, r_1) = \psi^{-1}(x)]. \quad (5)$$

Observe that [Equation 5](#) holds trivially if  $B_1$  makes no queries, since then both sides equal 0. Therefore it is enough to consider only the case where  $B_1$  makes at least one query. For any decision tree algorithm  $Q$  on three bits, which makes at least one query, we define the number  $\rho_Q$  as:

$$\rho_Q = \frac{\Pr_{x \in \mathbb{R}} \mathcal{H}_1^0[Q(x) \text{ queries } x_{m(x)}]}{\Pr_{x \in \mathbb{R}} \mathcal{H}_1^0[Q(x) \text{ queries } x_{r_1} \text{ where } (0, r_1) = \psi^{-1}(x)]}.$$

Note that the denominator is at least  $1/3$ , since  $Q$  queries  $x_{r_1}$  when  $x$  is such that  $r_1$  is the index of the first query. We prove that  $\rho_Q$  is always at least  $1/2$ , by describing a decision tree algorithm  $Q'$  which minimizes  $\rho_Q$ . The algorithm  $Q'$  is defined as follows:

- Query  $x_1$
- If  $x_1 = 0$ , stop
- If  $x_1 = 1$ , query  $x_2$  and stop.

**Claim 3.3.** *The algorithm  $Q'$  gives  $\rho_{Q'} = 1/2$ , and this is the minimal possible  $\rho_Q$  among all deterministic decision tree algorithms making at least one query.*

To prove the claim we first evaluate  $\rho_{Q'}$ . The numerator equals  $1/3$  since the minority is queried only when  $x = 100$ , while the denominator equals  $2/3$  since  $x_{r_1}$  is queried when  $x$  is 001 or 100.

Let now be  $Q$  any algorithm which makes at least one query, we prove that  $\rho_Q \geq 1/2$ . Without loss of generality, we may suppose that the first query is  $x_1$ . We distinguish two cases.

If  $Q$  makes a second query when the first query is evaluated to 0 then the numerator is at least  $2/3$  since for the second query there is also an  $x$  for which  $m(x)$  is the index of this query. But the denominator is at most 1, and therefore in that case  $\rho_Q \geq 2/3$ . If  $Q$  does not make a second query when the first query is evaluated to 0 then the denominator is at most  $2/3$  since for  $x = 010$ , we have  $r_1 = 3$ , but  $x_3$  is not queried. Since the numerator is at least  $1/3$ , we have in that case  $\rho_Q \geq 1/2$ .

To handle a general  $S$ , replace  $\{1, 2, 3\}$  with  $m(x)$  and its two siblings. For  $S$  such that  $x \in S$  satisfies  $x_{m(x)} = 0$ , the optimal algorithm  $Q'$  is the same as the one described above, except with each 0 changed to 1 and vice versa.

Therefore [Equation 5](#) holds for every  $B_1$ , which implies the theorem. □

Combining [Corollary 2.3](#) and [Theorem 3.1](#), we obtain the following.

**Corollary 3.4.**  $R^\delta(3\text{-MAJ}_h) \geq (1 - 2\delta)(5/2)^h$ .

We conjecture that this can be improved to  $R^\delta(3\text{-MAJ}_h) \geq (1 - 2\delta)2.54355^h$ . See [Section A](#) for details.

## 4 Improved depth-two algorithm

In this section, we present a new zero-error algorithm for computing  $3\text{-MAJ}_h$ . For the key ideas behind it, we refer the reader to [Section 1](#).

As before, we identify the formula  $3\text{-MAJ}_h$  with a complete ternary tree of height  $h$ . In the description of the algorithm we adopt the following convention. Once the algorithm has determined the value  $b$  of the subformula rooted at a node  $v$  of the formula  $3\text{-MAJ}_h$ , we also use  $v$  to denote this bit value  $b$ .

The algorithm is a combination of two depth-2 recursive algorithms. The first one, `EVALUATE`, takes a node  $v$  of height  $h(v)$ , and evaluates the subformula rooted at  $v$ . The interesting case, when  $h(v) > 1$ , is depicted in [Figure 1](#); a formal description is given as [Algorithm 2](#) in the appendix ([Section B](#)). The first step, permuting the input, means applying a random permutation to the children  $y_1, y_2, y_3$  of  $v$  and independent random permutations to each of the three sets of grandchildren.

The second algorithm, `COMPLETE`, is depicted in [Figure 2](#) and is described more formally as [Algorithm 3](#) in the appendix ([Section B](#)). It takes two arguments  $v, y_1$ , and completes the evaluation of the

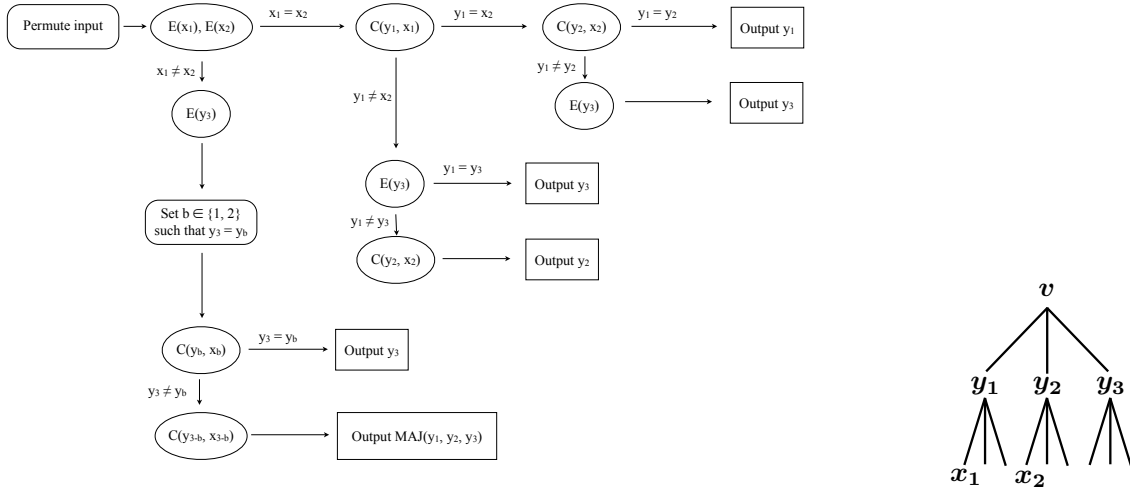

Figure 1: Pictorial representation of algorithm EVALUATE on a subformula of height  $h(v) \geq 2$  rooted at  $v$ . It is abbreviated by the letter ‘E’ when called recursively on descendants of  $v$ . The letter ‘C’ abbreviates the second algorithm COMPLETE.

subformula  $3\text{-MAJ}_h$  rooted at node  $v$ , where  $h(v) \geq 1$ , and  $y_1$  is a child of  $v$  whose value has already been evaluated. The first step, permuting the input, means applying a random permutation to the children  $y_2, y_3$  of  $v$  and independent random permutations to each of the two sets of grandchildren of  $y_2, y_3$ . Note that this is similar in form to the depth 2 algorithm of [5].

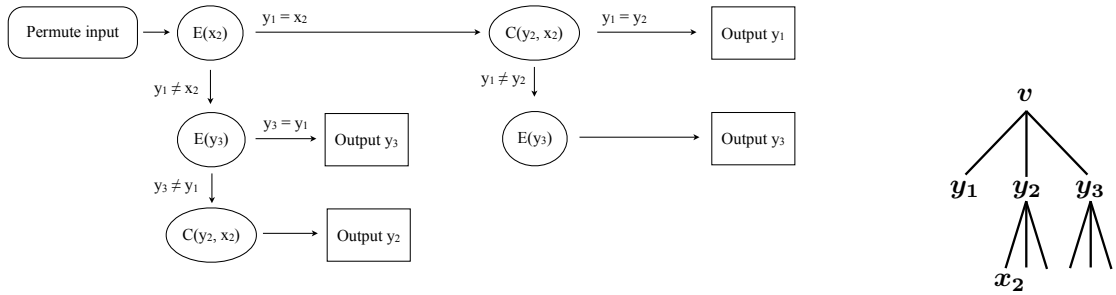

Figure 2: Pictorial representation of algorithm COMPLETE on a subformula of height  $h \geq 1$  rooted at  $v$  one child  $y_1$  of which has already been evaluated. It is abbreviated by the letter ‘C’ when called recursively on descendants of  $v$ . Calls to EVALUATE are denoted ‘E’.

To evaluate an input of height  $h$ , we invoke  $\text{EVALUATE}(r)$ , where  $r$  is the root. The correctness of the two algorithms follows by inspection—they determine the values of as many children of the node  $v$  as is required to compute the value of  $v$ .

For the complexity analysis, we study the expected number of queries they make for a worst-case input of fixed height  $h$ . Let  $T(h)$  be the worst-case complexity of  $\text{EVALUATE}(v)$  for  $v$  of height  $h$ . For  $\text{COMPLETE}(v, y_1)$ , we distinguish between two cases. Let  $y_1$  be the child of node  $v$  that has already been evaluated. The complexity given that  $y_1$  is the minority child of  $v$  is denoted by  $S^m$ , and the complexity given that it is a majority child is denoted by  $S^M$ .

The heart of our analysis is the following set of recurrences that relate  $T$ ,  $S^M$  and  $S^m$  to each other.

**Lemma 4.1.** *We have*

$$S^m(1) = 2, \quad S^M(1) = \frac{3}{2}, \quad T(0) = 1, \quad \text{and} \quad T(1) = \frac{8}{3}.$$

For all  $h \geq 1$ , we have

$$S^M(h) \leq S^m(h) \quad \text{and} \quad S^M(h) \leq T(h). \quad (6)$$

Finally, for all  $h \geq 2$ , we have

$$S^m(h) = T(h-2) + T(h-1) + \frac{2}{3}S^M(h-1) + \frac{1}{3}S^m(h-1), \quad (7)$$

$$S^M(h) = T(h-2) + \frac{2}{3}T(h-1) + \frac{1}{3}S^M(h-1) + \frac{1}{3}S^m(h-1), \quad \text{and} \quad (8)$$

$$T(h) = 2T(h-2) + \frac{23}{27}T(h-1) + \frac{26}{27}S^M(h-1) + \frac{18}{27}S^m(h-1). \quad (9)$$

*Proof.* We prove these relations by induction. The bounds for  $h \in \{0, 1\}$  follow immediately by inspection of the algorithms. To prove the statement for  $h \geq 2$ , we assume the recurrences hold for all  $l < h$ . Observe that it suffices to prove that Equations (7), (8), (9) for height  $h$ , since the values of the coefficients immediately imply that Inequalities (6) holds for  $h$  as well.

**Equation (7).** Since COMPLETE( $v, y_1$ ) always starts by computing the value of a grandchild  $x_2$  of  $v$ , we get the first term  $T(h-2)$  in Eq. (7). It remains to show that the worst-case complexity of the remaining queries is  $T(h-1) + (2/3)S^M(h-1) + (1/3)S^m(h-1)$ .

Since  $y_1$  is the minority child of  $v$ , we have that  $y_1 \neq y_2 = y_3$ . The complexity of the remaining steps is summarized in the next table in the case that the three children of node  $y_2$  are not all equal. In each line of the table, the worst case complexity is computed given the event in the first cell of the line. The second cell in the line is the probability of the event in the first cell over the random permutation of the children of  $y_2$ . This gives a contribution of  $T(h-1) + (2/3)S^M(h-1) + (1/3)S^m(h-1)$ .

$S^m(h)$ (we have $y_1 \neq y_2 = y_3$ )		
event	probability	complexity
$y_2 = x_2$	$2/3$	$T(h-1) + S^M(h-1)$
$y_2 \neq x_2$	$1/3$	$T(h-1) + S^m(h-1)$

This table corresponds to the worst case, as the only other case is when all children of  $y_2$  are equal, in which the cost is  $T(h-1) + S^M(h-1)$ . Applying Inequality (6) for  $h-1$ , this is a smaller contribution than the case where the children are not all equal.

Therefore the worst case complexity for  $S^m$  is given by Eq. (7). We follow the same convention and appeal to this kind of argument also while deriving the other two recurrence relations.

**Equation (8).** Since COMPLETE( $v, y_1$ ) always starts by computing the value of a grandchild  $x_2$  of  $v$ , we get the first term  $T(h-2)$  in Eq. (8). There are then two possible patterns, depending on whether the three children  $y_1, y_2, y_3$  of  $v$  are all equal. If  $y_1 = y_2 = y_3$ , we have in the case that all children of  $y_2$  are not equal that:

$S^M(h)$ if $y_1 = y_2 = y_3$		
event	probability	complexity
$y_2 = x_2$	$2/3$	$S^M(h-1)$
$y_2 \neq x_2$	$1/3$	$T(h-1)$

As in the above analysis of Eq. (7), applying Inequalities (6) for height  $h-1$  implies that the complexity in the case when all children of  $y_2$  are equal can only be smaller, therefore the above table describes the worst-case complexity for the case when  $y_1 = y_2 = y_3$ .

If  $y_1, y_2, y_3$  are not all equal, we have two events  $y_1 = y_2 \neq y_3$  or  $y_1 = y_3 \neq y_2$  of equal probability as  $y_1$  is a majority child of  $v$ . This leads to the following tables for the case where the children of  $y_2$  are not all equal

$S^M(h)$ given $y_1 = y_2 \neq y_3$		
event	probability	complexity
$y_2 = x_2$	2/3	$S^M(h - 1)$
$y_2 \neq x_2$	1/3	$T(h - 1) + S^m(h - 1)$

$S^M(h)$ given $y_1 = y_3 \neq y_2$		
event	probability	complexity
$y_2 = x_2$	2/3	$T(h - 1)$
$y_2 \neq x_2$	1/3	$T(h - 1) + S^m(h - 1)$

As before, one can apply Inequalities (6) for height  $h - 1$  to see that the worst case occurs when the children of  $y_2$  are not all equal.

From the above tables, we deduce that the worst-case complexity occurs on inputs where  $y_1, y_2, y_3$  are not all equal. This is because one can apply Inequalities (6) for height  $h - 1$  to see that, line by line, the complexities in the table for the case  $y_1 = y_2 = y_3$  are upper bounded by the corresponding entries in each of the latter two tables. To conclude Eq. (8), recall that the two events  $y_1 = y_2 \neq y_3$  and  $y_1 = y_3 \neq y_2$  occur with probability 1/2 each:

$$\begin{aligned}
S^M(h) &= T(h - 2) + \frac{1}{2} \left[ \frac{2}{3} S^M(h - 1) + \frac{1}{3} (T(h - 1) + S^m(h - 1)) \right] \\
&\quad + \frac{1}{2} \left[ \frac{2}{3} T(h - 1) + \frac{1}{3} (T(h - 1) + S^m(h - 1)) \right].
\end{aligned}$$

**Equation (9).** Since EVALUATE( $v$ ) starts with two calls to itself to compute  $x_1, x_2$ , we get the first term  $2T(h - 2)$  on the right hand side.

For the remaining complexity, we consider two possible cases, depending on whether the three children  $y_1, y_2, y_3$  of  $v$  are equal. If  $y_1 = y_2 = y_3$ , assuming that the children of  $y_1$  are not all equal, and the same for the children of  $y_2$ , we have

$T(h)$ given $y_1 = y_2 = y_3$		
event	probability	complexity
$y_1 = x_1, y_2 = x_2$	4/9	$2S^M(h - 1)$
$y_1 = x_1, y_2 \neq x_2$	2/9	$T(h - 1) + S^M(h - 1)$
$y_1 \neq x_1, y_2 = x_2$	2/9	$T(h - 1) + S^M(h - 1)$
$y_1 \neq x_1, y_2 \neq x_2$	1/9	$T(h - 1) + S^m(h - 1)$

As before, the complexities are in non-decreasing order, and we observe that Inequalities (6) for height  $h - 1$  implies that in a worst case input the children of  $y_1$  are not all equal, and the same for the children of  $y_2$ .

If  $y_1, y_2, y_3$  are not all equal, we have three events  $y_1 = y_2 \neq y_3$ ,  $y_1 \neq y_2 = y_3$  and  $y_3 = y_1 \neq y_2$  each of which occurs with probability 1/3. This leads to the following analyses

$T(h)$ given $y_1 = y_2 \neq y_3$		
event	probability	complexity
$y_1 = x_1, y_2 = x_2$	4/9	$2S^M(h - 1)$
$y_1 = x_1, y_2 \neq x_2$	2/9	$T(h - 1) + S^M(h - 1) + S^m(h - 1)$
$y_1 \neq x_1, y_2 = x_2$	2/9	$T(h - 1) + S^M(h - 1) + S^m(h - 1)$
$y_1 \neq x_1, y_2 \neq x_2$	1/9	$T(h - 1) + 2S^m(h - 1)$

$T(h)$ given $y_1 \neq y_2 = y_3$		
event	probability	complexity
$y_1 = x_1, y_2 = x_2$	4/9	$T(h - 1) + S^M(h - 1)$
$y_1 = x_1, y_2 \neq x_2$	2/9	$T(h - 1) + S^M(h - 1) + S^m(h - 1)$
$y_1 \neq x_1, y_2 = x_2$	2/9	$T(h - 1) + S^M(h - 1) + S^m(h - 1)$
$y_1 \neq x_1, y_2 \neq x_2$	1/9	$T(h - 1) + 2S^m(h - 1)$

$T(h)$ given $y_3 = y_1 \neq y_2$		
event	probability	complexity
$y_1 = x_1, y_2 = x_2$	4/9	$T(h-1) + S^M(h-1)$
$y_1 = x_1, y_2 \neq x_2$	2/9	$T(h-1) + S^M(h-1) + S^m(h-1)$
$y_1 \neq x_1, y_2 = x_2$	2/9	$T(h-1) + S^m(h-1)$
$y_1 \neq x_1, y_2 \neq x_2$	1/9	$T(h-1) + 2S^m(h-1)$

In all three events, we observe that Inequalities (6) for height  $h-1$  implies that in a worst case input, the children of  $y_1$  are not all equal, and the same for the children of  $y_2$ .

Applying Inequalities (6) for height  $h-1$ , it follows that line by line the complexities in the last three tables are at least the complexities in the table for the case  $y_1 = y_2 = y_3$ . Therefore the worst case also corresponds to an input in which  $y_1, y_2, y_3$  are not all equal. We conclude Eq. (9) as before, by taking the expectation of the complexities in the last three tables.  $\square$

**Theorem 4.2.**  $T(h), S^M(h)$ , and  $S^m(h)$  are all in  $O(\alpha^h)$ , where  $\alpha \leq 2.64946$ .

*Proof.* We make an ansatz that  $T(h) \leq a\alpha^h$ ,  $S^M(h) \leq b\alpha^h$ , and  $S^m(h) \leq c\alpha^h$ , and find constants  $a, b, c, \alpha$  for which we may prove these inequalities by induction.

The base cases tell us that

$$2 \leq c\alpha, \quad \frac{3}{2} \leq b\alpha, \quad 1 \leq a, \quad \text{and} \quad \frac{8}{3} \leq a\alpha. \quad (10)$$

Assuming we have constants that satisfy these conditions, and that the inequalities hold for all appropriate  $l < h$ , for some  $h \geq 2$ , we derive sufficient conditions for the inductive step to go through.

By the induction hypothesis and Lemma 4.1, we have

$$\begin{aligned} S^m(h) &\leq a\alpha^{h-2} + a\alpha^{h-1} + \frac{2b}{3}\alpha^{h-1} + \frac{c}{3}\alpha^{h-1}, \\ S^M(h) &\leq a\alpha^{h-2} + \frac{2a}{3}\alpha^{h-1} + \frac{b}{3}\alpha^{h-1} + \frac{c}{3}\alpha^{h-1}, \quad \text{and} \\ T(h) &\leq 2a\alpha^{h-2} + \frac{23a}{27}\alpha^{h-1} + \frac{26}{27}\alpha^{h-1} + \frac{18}{27}\alpha^{h-1}. \end{aligned}$$

These would imply the required bounds on  $S^m(h), S^M(h), T(h)$  if

$$\begin{aligned} a + \frac{3a + 2b + c}{3}\alpha &\leq c\alpha^2, \\ a + \frac{2a + b + c}{3}\alpha &\leq b\alpha^2, \quad \text{and} \\ 2a + \frac{23a + 26b + 18c}{27}\alpha &\leq a\alpha^2. \end{aligned} \quad (11)$$

The choice  $\alpha = 2.64946$ ,  $a = 1.007$ ,  $b = 0.55958a$ , and  $c = 0.75582a$  satisfies all the inequalities (10, 11), so that the proof by induction holds.  $\square$

## A A conjectured better lower bound

Our proof from the previous section proceeds by proving a recurrence, using a one level encoding scheme, for the minimal probability that an algorithm queries the absolute minority bit. One can ask whether this is the best possible recurrence, and the following theorem hints that it may be possible to improve it by using higher level encoding schemes. Unfortunately we are unable to prove a claim analogous to [Claim 3.3](#) in the case of such a recurrence, as the number of possible decision trees to minimize over is too large to handle by enumeration by hand. We nevertheless have a candidate for the minimal decision tree algorithm, which is the natural extension of the algorithm given in [Theorem 3.1](#) for the one level recursion, and we leave as an open question whether or not our candidate indeed achieves the minimum.

As before, the base case satisfies  $p_0^\delta \geq 1 - 2\delta$ . In the following, we omit  $\delta$  from the notation when convenient.

**Definition A.1.** A *two-level encoding scheme* is a map  $\psi$  for every  $h \geq 2$ , from  $\mathcal{H}_{h-2} \times \Omega$  to  $\mathcal{H}_h$  ( $\Omega$  is a space of random coins for the encoding), satisfying for every  $(y, \omega)$ :

$$3\text{-MAJ}_{h-1}(y) = 3\text{-MAJ}_h(\psi(y, \omega)).$$

**Theorem A.2.** *Assuming [Conjecture A.3](#), for every  $h \geq 0$ , we have*

$$p_h^\delta \geq (1 - 2\delta)(\sqrt{13/47})^h > (1 - 2\delta)0.5259^h.$$

*Proof.* The proof follows the same structure as that of [Theorem 3.1](#) but using two levels recursion: we show that  $(47/13)p_h \geq p_{h-2}$ . To prove this, for every deterministic algorithm  $A$  for height  $h$  formulae, we construct a randomized algorithm  $A'$  for height  $h - 2$  formulae such that the probability that  $A'$  queries the absolute minority is at most  $47/13$ -times the probability that  $A$  queries the absolute minority.

To define  $A'$ , we will use the two levels encoding scheme  $\psi : \mathcal{H}_{h-2} \times \{1, 2, 3\}^{4 \cdot 3^{h-2}} \rightarrow \mathcal{H}_h$ , induced by the same function  $c : \{0, 1\} \times \{1, 2, 3\} \rightarrow \mathcal{H}_1$  we have used for the one level encoding scheme in [Theorem 3.1](#). We recall that

$$c(y, r) = \begin{cases} y01 & \text{if } r = 1, \\ 1y0 & \text{if } r = 2, \\ 01y & \text{if } r = 3. \end{cases}$$

and we define the induced encoding  $\psi$  as follows: for every  $1 \leq i \leq 3^{h-2}$ ,

$$\psi(y, R, r_1, r_2, r_3)_{9i-8} \dots \psi(y, R, r_1, r_2, r_3)_{9i} = \begin{cases} c(y_i, r_{1i}), c(0, r_{2i}), c(1, r_{3i}) & \text{if } R_i = 1, \\ c(1, r_{1i}), c(y_i, r_{2i}), c(0, r_{3i}) & \text{if } R_i = 2, \\ c(0, r_{1i}), c(1, r_{2i}), c(y_i, r_{3i}) & \text{if } R_i = 3. \end{cases}$$

Let  $\Omega = \{1, 2, 3\}^{4 \cdot 3^{h-2}}$ , and we write  $\omega \in \Omega$  as  $\omega = (R, r_1, r_2, r_3)$ . On input  $y$ , by definition  $A'$  samples uniform  $\omega \in \Omega$  runs  $A$  on  $x = \psi(y, \omega)$ . As before, it suffices to prove that

$$(47/13) \Pr_{A, x \in \mathcal{H}_h} [A(x) \text{ queries } x_{m(x)}] \geq \Pr_{A', y \in \mathcal{H}_{h-2}, \omega \in \Omega} [A'(y, \omega) \text{ queries } y_{m(y)}] \quad (12)$$

We partition again  $\mathcal{H}_h$ , this time into sets of size 81. For  $h = 2$ , the two classes are  $\mathcal{H}_2^0$  and  $\mathcal{H}_2^1$ . For  $h > 2$ , the partition consists of the equivalence classes of the relation defined by  $x \sim x'$  if  $x_i = x'_i$  for all  $i$  such  $P(P(i)) \neq P(P(m(x)))$  in the tree  $T$ . Namely, an equivalence class consists of inputs that are identical everywhere except the 2-level subtree containing their absolute minority. We then prove that for every equivalence class  $S$ , and all  $B$  in the support of  $A$ , it holds that:

$$(47/13) \Pr_{x \in S} [B(x) \text{ queries } x_{m(x)}] \geq \Pr_{y, \omega} [B'(y, \omega) \text{ queries } y_{m(y)} \mid \psi(y, \omega) \in S]. \quad (13)$$

where  $B'$  is the algorithm that first computes  $x = \psi(y, \omega)$  and then evaluates  $B(x)$ .

To prove this, suppose for simplicity of notation  $m = m(x) \in \{1, \dots, 9\}$  and  $x_{m(x)} = 0$  for every  $x \in S$ . This implies that for all  $x \in S$ , if we set  $(y, \omega) = \psi^{-1}(x)$ , then  $m(y) = 1$  and  $y_1 = 0$ . Let  $B_2$  be the restriction of  $B$  to the first 9 bits, where for every query  $x_j$ , for  $j > 9$ , algorithm  $B_2$  follows the outgoing edge of  $B$  according the common value of the  $j$ th bit of the elements in  $S$ , and for each query  $x_j$  where  $j \in \{1, \dots, 9\}$ ,  $B_2$  also queries  $x_j$ .

Observe that  $B(x)$  querying  $x_{m(x)}$  corresponds to  $B_2(x)$  querying  $x_{m(x)}$ , while  $B'(y, \omega)$  querying  $y_{m(y)}$  corresponds to  $B_2(x)$  querying  $x_{q(x)}$ , where  $q(x) = 3(R_1 - 1) + r_{R_1}$  and where  $(0, (R_1, r_{11}, r_{21}, r_{31})) = \psi^{-1}(x)$ . Namely, if  $x = \psi(y, (R_1, r_{11}, r_{21}, r_{31}))$ , then  $q(x) \in \{1, \dots, 9\}$  is the location where the encoding inserted  $y_1$ .

Therefore [Equation 13](#) is equivalent to the following:

$$(47/13) \Pr_{x \in \mathcal{H}_2^0} [B_2(x) \text{ queries } x_{m(x)}] \geq \Pr_{x \in \mathcal{H}_2^0} [B_2(x) \text{ queries } x_{q(x)}] \quad (14)$$

For algorithms  $B_2$  that query no nodes, [Equation 14](#) is trivially satisfied as both sides equal 0. Therefore, we define for every decision tree algorithm  $Q$  on 9 bits which makes at least one query,  $\rho_Q$  as

$$\rho_Q = \frac{\Pr_{x \in \mathcal{H}_2^0} [Q(x) \text{ queries } x_{m(x)}]}{\Pr_{x \in \mathcal{H}_2^0} [Q(x) \text{ queries } x_{q(x)}]}. \quad (15)$$

Consider [Algorithm 1](#) on 9 variables. (See also [Figure 3](#) for a pictorial representation of the algorithm. In the figure, the symbol “ $\perp$ ” means stop, and “ALL” means to completely evaluate all variables, except the ones that cannot influence the output.)

We conjecture that the partial DT given in [Algorithm 1](#) is the tree that minimizes the LHS of this inequality. (See also [Figure 3](#) for a pictorial representation of the algorithm. In the figure, the symbol “ $\perp$ ” means stop, and “ALL” means to completely evaluate all variables, except ones that cannot influence the output.)

Figure 3: Picture of Algorithm 1

**Conjecture A.3.** *The algorithm given in Algorithm 1 (see also Figure 3) minimizes  $\rho_{B_2}$ .*

Assuming this conjecture, we now prove that Algorithm 1 achieves  $\rho_{B_2} = (13/47)$ . We refer to Figure 4, where we annotate the decision tree of Figure 3 with two numbers (inside the boxes). For each node  $v$ , right-side number is the number of choices of  $\omega$  such that the query at  $v$  is  $x_{q(x)}$ . The left-side count is the number of choices of  $x_1, \dots, x_9$  such that the query at  $v$  is the absolute minority among  $x_1, \dots, x_9$ .

We give a brief explanation of the counts, and leave the complete verification to the reader. First we consider the left-side counts: we assumed that the input evaluates to 0, so since the tree has height 2, the absolute minority has value 0. Therefore, we see that the only queries that might query the absolute minority are  $x_1, x_4, x_7$  (since for all other queries, either we are not in the minority subtree, or if we are in the minority subtree then we have already queried the sole 0 in that subtree). We can verify for example that there are 9 hard inputs on which  $x_1$  is the absolute minority:  $(x_1, \dots, x_9) = 011\ 001\ 001$  and the eight other inputs obtained by permuting  $x_4, x_5, x_6$  and permuting  $x_7, x_8, x_9$ .

For the right-side counts, we observe that in general they are significantly larger because  $x_{q(x)}$  is a *majority* node. For instance, for the right-side count on the node marked  $x_3$ , there are 9 inputs on which  $x_1 = 0$  and  $x_2 = 1$ , and  $q(x) = 3$ . Namely, when  $R_1 = 1, r_{11} = 3$ , and  $r_{21}, r_{31}$  are free (there are 9 possibilities).

The sum of the left-hand counts is 13 and the sum of the right-hand counts is 47. This gives a ratio of  $13/47$ . To lift our assumptions on  $S$ , it suffices to look at the set of all grandchildren of  $M(S)_{h-2}$  rather than leaves  $\{1, \dots, 9\}$ , and if the value of  $m(x) = 1$  for  $x \in S$ , then it suffices to use Algorithm 1 except flipping all the 0's to 1's and vice versa. □

**Theorem A.4.** *Assuming Conjecture A.5, for every  $h \geq 0$ , we have*

$$p_h^\delta \geq (1 - 2\delta)(\sqrt{13/44})^h > (1 - 2\delta)0.54355^h.$$

*Proof.* This theorem uses a two-level encoding that is more symmetric than that of Theorem A.2. Let  $c$  be as in the proof of Theorem A.2. We build the following encoding, where  $(b, R, r_1, r_2, r_3) \in \{0, 1\}^{3^{h-2}} \times \{1, 2, 3\}^{4 \cdot 3^{h-2}}$ :

$$\psi(y, b, R, r_1, r_2, r_3)_{9i-8} \dots \psi(y, R, r_1, r_2, r_3)_{9i} = \begin{cases} c(y_i, r_{1i}), c(b, r_{2i}), c(1 - b, r_{3i}) & \text{if } R_i = 1, \\ c(1 - b, r_{1i}), c(y_i, r_{2i}), c(b, r_{3i}) & \text{if } R_i = 2, \\ c(b, r_{1i}), c(1 - b, r_{2i}), c(y_i, r_{3i}) & \text{if } R_i = 3. \end{cases}$$

Figure 4: Algorithm 1, annotated for [Theorem A.2](#)

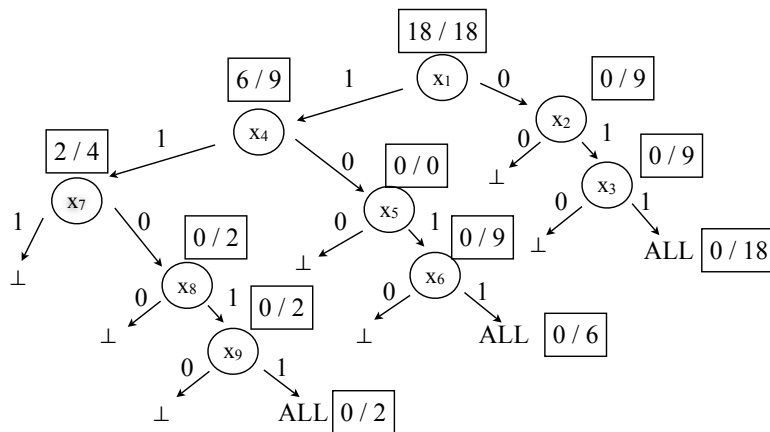

Figure 5: Algorithm 1, annotated for [Theorem A.4](#)

We note that this encoding  $\psi$  is no longer a bijection. However, one can make essentially the same argument as [Theorem A.2](#) to show that it suffices to prove that the following ratio is at least  $13/44$  for all decision trees  $Q$  on 9 variables:

$$\rho_Q = \frac{\Pr_{x \in \mathcal{H}_2^0}[Q(x) \text{ queries } x_{m(x)}]}{\Pr_{x \in \mathcal{H}_2^0, q(x)}[Q(x) \text{ queries } x_{q(x)}]}. \quad (16)$$

where  $q(x) = 3(R_1 - 1) + r_{R_1}$  and where  $(0, (b_1, R_1, r_{11}, r_{21}, r_{31}))$  is uniformly sampled among the set of preimages  $\psi^{-1}(x)$ .

**Conjecture A.5.** *The algorithm of [Figure 3](#) (see also [Figure 3](#)) minimizes  $\rho_Q$ , with value equal to  $13/44$ .*

Our candidate algorithm minimizing Eq. (16) is also the same, and the counts (analogous to those given in [Figure 4](#) for the the proof of [Theorem A.2](#)) are given in [Figure 5](#). (To make the left and right-hand quantities comparable, we multiplied left-hand counts by 2. This is because the probability space of  $x$  is half the size of the probability space of  $x, q(x)$ ). This leads to a ratio of  $13/44$ .  $\square$

### A.1 Intuition behind the conjecture

We believe the conjectures [Conjecture A.3](#) and [Conjecture A.5](#) because they represent a natural strategy for minimizing the ratio  $\rho_Q$ . Namely, the algorithm in [Figure 3](#) encodes the strategy that we query the nodes in order, but we skip nodes that have increased probability of being the absolute minority. This occurs for instance with the first query  $x_1$ : if  $x_1 = 0$  then we know that the next query cannot be the absolute minority (since the absolute minority has value 0 and it is the unique leaf in its subtree with value 0), so we are comfortable querying  $x_2$ . If  $x_1 = 1$ , then there is an increased probability that  $x_2$  is the absolute minority, so we skip it and move to  $x_4$ , which is in the next subtree. This strategy also occurs at depth 1 from the root: if we evaluate  $y_1 = 1$  then we know that the absolute minority must be a child of  $y_1$ , so we can safely evaluate all the children of  $y_2, y_3$ . On the other hand, if  $y_1 = 0$ , then there is the absolute minority must be a child of  $y_2$  or  $y_3$ , and we stop evaluating in order to avoid evaluating the absolute minority.

## B Formal description of the algorithms

In this section we present a formal description of the depth-two recursive algorithms for  $3\text{-MAJ}_h$  studied in [Section 4](#). Pieces corresponding to  $h \geq 2$  are depicted in [Figures 1](#) and [2](#).

---

**Algorithm 1** Conjectured optimal partial DT for [Equation 15](#), see [Figure 3](#)

---

```
evaluate  $x_1$ 
if  $x_1 = 0$  then
  evaluate  $x_2$ 
  if  $x_2 = 0$  then
    stop
  else
    evaluate  $x_3$ 
    if  $x_3 = 0$  then
      stop
    else
      exhaustively evaluate remaining variables
    end if
  end if
else if
else
  evaluate  $x_4$ 
  if  $x_4 = 0$  then
    evaluate  $x_5$ 
    if  $x_5 = 0$  then
      stop
    else
      evaluate  $x_6$ 
      if  $x_6 = 0$  then
        stop
      else
        exhaustively evaluate remaining variables
      end if
    end if
  end if
else
  evaluate  $x_7$ 
  if  $x_7 = 0$  then
    evaluate  $x_8$ 
    if  $x_8 = 0$  then
      stop
    else
      evaluate  $x_9$ 
      if  $x_9 = 0$  then
        stop
      else
        exhaustively evaluate remaining variables
      end if
    end if
  end if
end if
end if
end if
```

---

**Algorithm 2** EVALUATE( $v$ ): evaluate a node  $v$ .

---

**Input:** Node  $v$  with subtree of height  $h(v)$ .

**Output:** the bit value  $3\text{-MAJ}_h(Z(v))$  of the subformula rooted at  $v$

Let  $h = h(v)$

{First base case:  $h = 0$  ( $v$  is a leaf)}

**if**  $h = 0$  **then**

    Query  $Z(v)$  to get its value  $a$

**return**  $a$

**end if**

Let  $y_1, y_2, y_3$  be a uniformly random permutation of the children of  $v$

{Second base case:  $h = 1$ }

**if**  $h = 1$  **then**

    EVALUATE( $y_1$ ) and EVALUATE( $y_2$ )

**if**  $y_1 = y_2$  **then**

**return**  $y_1$

**else**

**return** EVALUATE( $y_3$ )

**end if**

**end if**

{Recursive case}

Let  $x_1$  and  $x_2$  be chosen uniformly at random from the children of  $y_1$  and  $y_2$ , respectively

{use the attached figure as a guide}

EVALUATE( $x_1$ ) and EVALUATE( $x_2$ )

**if**  $x_1 \neq x_2$  **then**

    EVALUATE( $y_3$ )

    Let  $b \in \{1, 2\}$  be such that  $x_b = y_3$

    COMPLETE( $y_b, x_b$ )

**if**  $y_b = y_3$  **then**

**return**  $y_b$

**else**

**return** COMPLETE( $y_{3-b}, x_{3-b}$ )

**end if**

**else**  $\{x_1 = x_2\}$

    COMPLETE( $y_1, x_1$ )

**if**  $y_1 = x_1$  **then**

        COMPLETE( $y_2, x_2$ )

**if**  $y_2 = x_2$  **then**  $\{y_2 = y_1\}$

**return**  $y_1$

**else**  $\{y_2 \neq y_1\}$

**return** EVALUATE( $y_3$ )

**end if**

**else**  $\{y_1 \neq x_1\}$

        EVALUATE( $y_3$ )

**if**  $y_3 = y_1$  **then**

**return**  $y_1$

**else**

**return** COMPLETE( $y_2, x_2$ )

**end if**

**end if**

**end if**

---

**Algorithm 3** COMPLETE( $v, y_1$ ): finish the evaluation of the subformula rooted at node  $v$ 

---

**Input:** Node  $v$  of height  $h(v)$ ; child  $y_1$  of  $v$  which has already been evaluated**Output:** the bit value  $3\text{-MAJ}_h(Z(v))$ Let  $h = h(v)$ Let  $y_2, y_3$  be a uniformly random permutation of the two children of  $v$  other than  $y_1$ 

{Base case}

**if**  $h = 1$  **then**    EVALUATE( $y_2$ )    **if**  $y_2 = y_1$  **then**        **return**  $y_1$     **else**        **return** EVALUATE( $y_3$ )    **end if****end if**

{Recursive case}

Let  $x_2$  be chosen uniformly at random from the children of  $y_2$ 

{use the attached figure as a guide}

EVALUATE( $x_2$ )**if**  $y_1 \neq x_2$  **then**    EVALUATE( $y_3$ )    **if**  $y_1 = y_3$  **then**        **return**  $y_1$     **else**        **return** COMPLETE( $y_2, x_2$ )    **end if****else**  $\{y_1 = x_2\}$     EVALUATE( $y_2, x_2$ )    **if**  $y_1 = y_2$  **then**        **return**  $y_1$     **else**        **return** EVALUATE( $y_3$ )    **end if****end if**
