Abstract

Oblivious transfer is a fundamental primitive in cryptography. While perfect information theoretic security is impossible, quantum oblivious transfer protocols can limit the dishonest players’ cheating. Finding the optimal security parameters in such protocols is an important open question. In this paper we show that every 1-out-of-2 oblivious transfer protocol allows a dishonest party to cheat with probability bounded below by a constant strictly larger than $\frac{1}{2}$. Alice’s cheating is defined as her probability of guessing Bob’s index, and Bob’s cheating is defined as his probability of guessing both input bits of Alice. In our proof, we relate these cheating probabilities to the cheating probabilities of a coin flipping protocol and conclude by using Kitaev’s coin flipping lower bound. Then, we present an oblivious transfer protocol with two messages and cheating probabilities at most $\frac{3}{4}$. Last, we extend Kitaev’s semidefinite programming formulation to more general primitives, where the security is against a dishonest player trying to force the outcome of the other player, and prove optimal lower and upper bounds for them.

1 Introduction

Quantum information enables us to do cryptography with information theoretic security. The first breakthrough result in quantum cryptography is the unconditionally secure key distribution protocol of Bennett and Brassard [BB84]. Since then, a long series of work has studied which other cryptographic primitives are possible in the quantum world. However, the subsequent results were negative. Mayers and Lo, Chau proved the impossibility of secure ideal quantum bit commitment and oblivious transfer and consequently of any type of two-party secure computation [May97, LC97, DKSW07]. On the other hand, several imperfect variants of these primitives have been shown to be possible. Finding the optimal parameters for such fundamental primitives has been since an important open question. The reason for looking at these abstract primitives is that they are the basis for all cryptographic protocols one may wish to construct, including identification schemes, digital signatures, electronic voting, etc. Let us emphasize that in this paper we only look at information theoretic security and we do not discuss computational security or security in restricted models like the bounded-storage or noisy-storage model.

We start with coin flipping, which was first proposed by Blum [Blu81] and has since found numerous applications in two-party secure computation. Even though the results of Mayers and of Lo and Chau exclude the possibility of perfect quantum coin flipping, i.e., where the resulting coin is perfectly unbiased, it still remained open whether one can construct

\textsuperscript{*} This work was partially supported by the projects ANR-09-JCJC-0067-01, ANR-08-EMER-012, CSQIP EU-Canada Collaboration, NSERC, MITACS, and ERA (Ontario)
a quantum protocol where no player could bias the coin with probability 1. Aharonov et al. [ATVY00] provided such a protocol where no dishonest player could bias the coin with probability higher than 0.9143. Then, Ambainis [Amb01] described an improved protocol whose cheating probability was at most 3/4. Subsequently, a number of different protocols had been proposed [SR01, NS03, KN04] that achieved the same bound of 3/4.

On the other hand, Kitaev [Kit03], using a formulation of quantum coin flipping as semidefinite programs proved a lower bound of $1/2$ on the product of the cheating probabilities for Alice and Bob (see [ABDR04]). In other words, no quantum coin flipping protocol can achieve a cheating probability less than $1/\sqrt{2}$ for both Alice and Bob.

The question of whether 3/4 or $1/\sqrt{2}$ was the right answer has recently been resolved by Chailloux and Kerenidis [CK09] who described a protocol with cheating probability arbitrarily close to $1/\sqrt{2}$. In their protocol they use as a subroutine a weaker variant of coin flipping which is referred to as weak coin flipping.

In this paper, we focus on oblivious transfer, which is a universal primitive for any two-party secure computation [Rab81, EGL82, Cré87]. We define a 1-out-of-2 random oblivious transfer protocol with bias $\varepsilon$, denoted here as random-OT.

The first impossibility result for quantum OT with information theoretic security was shown by Lo [Lo97]. However, not much was known about the best possible bias that one can get for OT. Note that Kitaev’s lower bound does not a priori hold for OT, since we do not know how to easily convert an OT protocol to a coin flipping protocol without any loss.

In related work, Salvail, Schaffner and Sotakova [SSS09] have quantitatively studied a different notion of security for OT protocols (and generally any two-party protocols) that they call information leakage. They prove, among other results, that any 1-out-of-2 OT protocol has a constant leakage. Their model is somewhat different, for example they do not allow the players to abort during the protocol, and their security notion is described in terms of mutual information and entropy and does not immediately translate to our security notion of guessing probabilities. However, their results provide more evidence that almost-perfect OT protocols are impossible for different variants of security.

In another work, Jain, Radhakrishnan and Sen [JRS02] showed that in a 1-out-of-$n$ OT protocol, if Alice gets $t$ bits of information about Bob’s index $b$, then Bob gets at least $\Omega(n/2^{O(t)})$ bits of information about Alice’s string $x$.

Our work

In this paper, we quantitatively study the bias of quantum oblivious transfer protocols. More precisely, we construct a coin flipping protocol that uses OT as a subroutine and show a relation between the cheating probabilities of the OT protocol and the ones of the coin flipping protocol. Then, using Kitaev’s lower bound for coin flipping we derive a non-trivial lower bound (albeit weaker) on the cheating probabilities for OT. More precisely we prove the following theorem.

$\blacktriangleright$ Theorem 1. In any quantum oblivious transfer protocol, we have

$$A_{OT} \cdot f(B_{OT}) \geq 1/2$$

where $f$ is a function that we define later$^1$. This implies for the bias $\varepsilon$ of the protocol that

$$\varepsilon \geq \frac{1}{2} \left( \sqrt{\frac{1}{2} + 2\sqrt{2}} - \sqrt{\frac{1}{2}} \right) - \frac{1}{2} \approx 0.0586.$$

$^1$ $f$ is the inverse of the function $g(x) = x(2x - 1)^2$ on some domain
Moreover, in Section 4 we describe a simple 1-out-of-2 random-OT protocol and analyze the cheating probabilities of Alice and Bob.

▶ Theorem 2. There exists a quantum oblivious transfer protocol such that $A_{OT} = B_{OT} = \frac{3}{4}$.

One may wonder if it would be possible to extend Kitaev’s semidefinite programming formulation to include the OT primitive and get a stronger lower bound this way. In Section 5 we describe a generalization of Kitaev’s semidefinite program that captures a variant of the general $k$-out-of-$n$ OT primitive. Coin flipping, is then the special case of 1-out-of-1 OT. However, there is a big difference. What the semidefinite program formulation captures is the probability that one player can force the outcome of the other one. More precisely, we define a $k$-out-of-$n$ forcing oblivious transfer protocol, denoted here as $(\binom{n}{k})$-fOT.

We show the following theorem.

▶ Theorem 3. In any $(\binom{n}{k})$-fOT protocol and consistent $b, x, x_b$ we have

$$A_{b, x_b} \leq \frac{\sqrt{2^k} (1 + \gamma)}{(\binom{n}{k}) \cdot 2^k}$$

and

$$B_x \leq \frac{\sqrt{2^k} (1 + \gamma)}{2^n}.$$

Note that for the special case of coin flipping, or else $(\binom{1}{1})$-fOT, our bounds are tight (a multiplicative bias of $\sqrt{2}$ is equivalent to a cheating probability of $\frac{1}{\sqrt{2}}$).

Similar to coin flipping, one can get optimal protocols as well for $(\binom{n}{k})$-fOT.

▶ Theorem 4. Let $\gamma > 0$. There exists a protocol for $(\binom{n}{k})$-fOT with cheating probabilities:

$$A_{b, x_b} \leq \frac{\sqrt{2^k} (1 + \gamma)}{(\binom{n}{k}) \cdot 2^k}$$

and

$$B_x \leq \frac{\sqrt{2^k} (1 + \gamma)}{2^n}.$$

2 Preliminaries

In the literature, many different variants of oblivious transfer have been considered. In this paper, we mainly consider random oblivious transfer. In the full version, we show how this definition is equivalent to other definitions of oblivious transfer with respect to the bias $\varepsilon$.

▶ Definition 5 (Random Oblivious Transfer). A 1-out-of-2 quantum random oblivious transfer protocol with bias $\varepsilon$, denoted here as random-OT, is a protocol between Alice and Bob such that:

- Alice outputs two bits $(x_0, x_1)$ or Abort and Bob outputs two bits $(b, y)$ or Abort
- If Alice and Bob are honest, they never Abort, $y = x_b$, Alice has no information about $b$ and Bob has no information about $x_b$. Also, $x_0, x_1, b$ are uniformly random bits
- $A_{OT} := \sup\{\Pr[\text{Alice guesses } b \text{ and Bob does not Abort}]\} = \frac{1}{2} + \varepsilon_A$
- $B_{OT} := \sup\{\Pr[\text{Bob guesses } (x_0, x_1) \text{ and Alice does not Abort}]\} = \frac{1}{2} + \varepsilon_B$
- The bias of the protocol is defined as $\varepsilon := \max\{\varepsilon_A, \varepsilon_B\}$

where the suprema are taken over all cheating strategies for Alice and Bob.

Note that this definition is slightly different from usual definitions because we want the exact value of the cheating probabilities and not only an upper bound. This is because we consider both lower bounds and upper bounds for OT protocols but we could have equivalent results using the standard definitions.
An important issue is that we quantify the security against a cheating Bob as the probability that he can guess \((x_0, x_1)\). One can imagine a security definition where Bob’s guessing probability is not for \((x_0, x_1)\), but for example for \(x_0 \oplus x_1\) or any other function \(f(x_0, x_1)\). Since we are mostly interested in lower bounds, we believe our definition is the most appropriate one, since a lower bound on the probability of guessing \((x_0, x_1)\) automatically yields a lower bound on the probability of guessing any \(f(x_0, x_1)\).

Note also that we do not have composability requirements for such protocols. Our main goal here is to get a constant lower bound for the simplest definition of OT, hence making the result as strong as possible. This is why we use the stand-alone definition. This is also the definition that one can relate most easily to the coin flipping protocols, which are also defined in a stand-alone way, e.g., in Kitaev’s bound.

We also define quantum (strong) coin flipping.

\textbf{Definition 6.} A quantum coin flipping protocol with bias \(\varepsilon\), denoted here as \(CF\), is a protocol between Alice and Bob who agree on an output \(a \in \{0, 1, \text{Abort}\}\) such that:

1. If Alice and Bob are honest then \(\Pr[a = 0] = \Pr[a = 1] = \frac{1}{2}\)
2. \(A_{CF} := \sup \{\max \{\Pr[a = 0], \Pr[a = 1]\}\} = \frac{1}{2} + \varepsilon_A\)
3. \(B_{CF} := \sup \{\max \{\Pr[a = 0], \Pr[a = 1]\}\} = \frac{1}{2} + \varepsilon_B\)
4. The bias of the protocol is defined as \(\varepsilon := \max \{\varepsilon_A, \varepsilon_B\}\)

where the suprema are taken over all strategies for Alice and Bob.

\section{A Lower Bound on Any Oblivious Transfer Protocol}

In this section we prove that the bias of any random-OT protocol, and hence any OT protocol, is bounded below by a constant. We start from a random-OT protocol and first show how to construct a coin flipping protocol. Then, we prove a relation between the cheating probabilities of the coin flipping protocol and those in the random-OT protocol. Last, we use Kitaev’s lower bound for coin flipping to derive a lower bound for any OT protocol.

\subsection{From Oblivious Transfer to Coin Flipping}

\textbf{Coin Flipping Protocol via random-OT}

1. Alice and Bob perform the OT protocol to create \((x_0, x_1)\) and \((b, x_b)\) respectively. If the OT protocol is aborted then so is the coin flipping protocol.
2. Alice sends \(c \in_R \{0, 1\}\) to Bob.
3. Bob sends \(b\) and \(x_b\) to Alice.
4. If \(x_b\) from Bob is consistent with Alice’s bits then the output of the protocol is \(c \oplus b\). Otherwise Alice aborts.

By definition, \(A_{OT}\) and \(B_{OT}\) denote the optimal cheating probabilities for Alice and Bob in the random-OT protocol and \(A_{CF}\) and \(B_{CF}\) denote the optimal cheating probabilities for Alice and Bob in the coin flipping protocol. Kitaev’s lower bound on coin flipping implies that \(A_{CF} B_{CF} \geq 1/2\). We use this inequality to derive an inequality involving \(A_{OT}\) and \(B_{OT}\).
Theorem 1. In any quantum oblivious transfer protocol, we have
\[ A_{OT} \cdot f(B_{OT}) \geq \frac{1}{2} \]
for the function \( f \) defined as:
\[
f(z) = \frac{1}{6} (3\sqrt{3}\sqrt{27z^2 - 2z + 27z - 1})^{1/3} + \frac{1}{6} (3\sqrt{3}\sqrt{27z^2 - 2z + 27z - 1})^{-1/3} + 1/3.
\]
This implies that the bias \( \varepsilon \) of the protocol satisfies
\[
\varepsilon \geq \frac{1}{4} \left( \frac{1}{2} + \sqrt{2} - \frac{1}{2} \approx 0.0586.
\]
In what follows we prove the above theorem.

Let \( \neg \bot^A_{CF} \) (resp. \( \neg \bot^B_{CF} \)) denote the event “Alice (resp. Bob) does not abort during the entire coin flipping protocol”. Let \( \neg \bot^A_{OT} \) (resp. \( \neg \bot^B_{OT} \)) denote the event “Alice (resp. Bob) does not abort during the random-OT subroutine”.

Cheating Alice
By definition, \( A_{OT} \) is the optimal probability of Alice guessing \( b \) in the random-OT protocol without Bob aborting. Suppose Alice desires to force 0 in the coin flipping protocol (a similar argument can be made if she wants 1). Bob must not abort and Alice must send \( c = b \) in her last message. Notice also that in our coin flipping protocol, honest Bob only aborts in the OT subroutine and hence \( \neg \bot^A_{OT} \equiv \neg \bot^B_{OT} \).

Thus,
\[
A_{CF} = \sup \{ \Pr[ (Alice sends c = b) \land \neg \bot^B_{CF} ] \} = \sup \{ \Pr[ (Alice guesses b) \land \neg \bot^B_{OT} ] \} = A_{OT}.
\]
where the suprema are taken over all possible strategies for Alice.

Cheating Bob
By definition, \( B_{OT} \) is the optimal probability of Bob learning both bits in the random-OT protocol without Alice aborting. Thus,
\[
B_{OT} = \sup \{ \Pr[ (Bob guesses (x_0, x_1)) \land \neg \bot^A_{OT} ] \}
= \sup \{ \Pr[\neg \bot^A_{OT}] \cdot \Pr[ (Bob guesses (x_0, x_1))|\neg \bot^A_{OT}] \},
\]
where the suprema are taken over all strategies for Bob.

If Bob wants to force 0 in the coin flipping protocol (a similar argument works if he wants to force 1), then first, Alice must not abort in the random-OT protocol and second, Bob must send \( b = c \) as well as the correct \( x_c \), such that Alice does not abort in the last round of the coin flipping protocol. This is equivalent to saying that Bob succeeds if he guesses \( x_c \) and Alice does not abort in the random-OT protocol. Since \( c \) is chosen by Alice uniformly at random, we can write the probability of Bob cheating as
\[
B_{CF} = \max \left\{ \frac{1}{2} \Pr[ (Bob guesses x_0) \land \neg \bot^B_{OT} ] + \frac{1}{2} \Pr[ (Bob guesses x_1) \land \neg \bot^B_{OT} ] \right\}
= \max \left\{ \Pr[\neg \bot^B_{OT}] \cdot \left( \frac{1}{2} \Pr[ (Bob guesses x_0)|\neg \bot^B_{OT} ] + \frac{1}{2} \Pr[ (Bob guesses x_1)|\neg \bot^B_{OT} ] \right) \right\}.
\]

\(^2 \) \( f \) is the inverse function of \( g(x) = x(2x - 1)^2 \) on some domain, see the proof for more details.
Notice that we use “max” instead of “sup” above. This is because an optimal strategy exists for every coin flipping protocol. This is a consequence of strong duality in the semidefinite programming formalism of [Kit03], see [ABDR04] for details.

Let us now fix Bob’s optimal cheating strategy in the CF protocol. For this strategy, let $p = \Pr[(\text{Bob guesses } x_0) | \neg \bot_A^{QT}]$, $q = \Pr[(\text{Bob guesses } x_1) | \neg \bot_A^{QT}]$ and $a = \frac{p+q}{2}$. Note that wlog, we can assume that Bob’s measurements are projective measurements. This can be done by increasing the dimension of Bob’s space. Also, Alice has a projective measurement on her space to determine the bits $(x_0, x_1)$.

We use the following lemma to relate $B_{CF}$ and $B_{OT}$.

**Lemma 1 (Learning-In-Sequence Lemma).** Let $p, q \in [1/2, 1]$. Let Alice and Bob share a joint pure state. Suppose Alice performs a projective measurement $M = \{M_{x_0, x_1}\}_{x_0, x_1} \in \{0, 1\}$ on her space to determine the values of $(x_0, x_1)$. Suppose there is a projective measurement $P = \{P_0, P_1\}$ on Bob’s space that allows him to guess bit $x_0$ with probability $p$ and a projective measurement $Q = \{Q_0, Q_1\}$ on his space that allows him to guess bit $x_1$ with probability $q$. Then, there exists a measurement on Bob’s space that allows him to guess $(x_0, x_1)$ with probability at least $a(2a - 1)^2$ where $a = \frac{p+q}{2}$.

We postpone the proof of this lemma to Subsection 3.2.

We now construct a cheating strategy for Bob for the OT protocol: run the optimal cheating CF strategy and look at Bob’s state after step 1 conditioned on $\neg \bot_A^{QT}$. Note that this event happens with nonzero probability in the optimal coin flipping strategy since otherwise the success probability is 0. The optimal CF strategy gives measurements that allow Bob to guess $x_0$ with probability $p$ and $x_1$ with probability $q$. Bob uses these measurements and the procedure of Lemma 1 to guess $(x_0, x_1)$. Let $b$ be the probability he guesses $(x_0, x_1)$. From Lemma 1, we have that $b \geq a(2a - 1)^2$. By definition of $B_{OT}$ and $B_{CF}$, we have:

$$b = \Pr[(\text{Bob guesses } (x_0, x_1)) | \neg \bot_A^{QT}] \leq \frac{B_{OT}}{\Pr[\neg \bot_A^{QT}]} \quad \text{and} \quad a = \frac{B_{CF}}{\Pr[\neg \bot_A^{QT}]}.$$  

This gives us

$$\frac{B_{OT}}{\Pr[\neg \bot_A^{QT}]} \geq \frac{B_{CF}}{\Pr[\neg \bot_A^{QT}] \left( \frac{2}{\Pr[\neg \bot_A^{QT}]} - 1 \right)^2} \quad \Rightarrow \quad B_{OT} \geq B_{CF} \left(2B_{CF} - 1\right)^2,$$

where the implication holds since $B_{CF} \geq 1/2$.

We now calculate an upper bound on $B_{CF}$ as a function of $B_{OT}$. Let $g(x) = x(2x - 1)^2$. It can be easily checked that $g$ is bijective on the interval $[0.5, 1]$ and increasing. Let $f$ be the inverse function of $g$ from $[0, 1]$ to $[0, 0.5]$. Since $g$ is increasing, $f$ is also increasing. Hence, since $B_{OT} \geq g(B_{CF})$ and $B_{CF} \in [0.5, 1]$, we conclude that

$$B_{CF} \leq f(B_{OT}).$$

We can write $f$ analytically using computer software to get the following function

$$f(z) = \frac{1}{6} (3\sqrt{3} \sqrt{27z^2 - 2z + 27z - 1})^{1/3} + \frac{1}{6} (3\sqrt{3} \sqrt{27z^2 - 2z + 27z - 1})^{-1/3} + 1/3.$$  

Kitaev’s lower bound states that $A_{CF} B_{CF} \geq 1/2$. From this, we have

$$A_{OT} f(B_{OT}) \geq A_{CF} B_{CF} \geq 1/2.$$
We now proceed to give the lower bound for the bias. Since $f$ is increasing, we have
\[(\varepsilon + 1/2) \cdot f(\varepsilon + 1/2) \geq A_{\text{OT}} f(B_{\text{OT}}) \geq A_{\text{CF}} B_{\text{CF}} \geq 1/2.\]
Solving the inequality we show that $\varepsilon$ must satisfy
\[\varepsilon \geq \frac{1}{2} \left( \sqrt{\frac{1}{2} + 2\sqrt{2}} - \sqrt{\frac{1}{2}} \right) - \frac{1}{2} \approx 0.0586.\]

3.2 Proof of the Learning-In-Sequence Lemma

The Learning-in-Sequence Lemma follows from the following simple geometric result.

**Proposition 2.** Let $|\psi\rangle$ be a pure state and let $\{C, I - C\}$ and $\{D, I - D\}$ be two projective measurements such that
\[\cos^2(\theta) := ||C|\psi\rangle||^2 \geq \frac{1}{2} \quad \text{and} \quad \cos^2(\theta') := ||D|\psi\rangle||^2 \geq \frac{1}{2}.\]
Then we have
\[||DC|\psi\rangle||^2 \geq \cos^2(\theta) \cos^2(\theta + \theta').\]

**Proof.** Define the following states
\[|X\rangle := \frac{C|\psi\rangle}{||C|\psi\rangle||}, \quad |X'\rangle := \frac{(I - C)|\psi\rangle}{||(I - C)|\psi\rangle||}, \quad |Y\rangle := \frac{D|\psi\rangle}{||D|\psi\rangle||}, \quad |Y'\rangle := \frac{(I - D)|\psi\rangle}{||(I - D)|\psi\rangle||}.\]
Then we can write $|\psi\rangle = \cos(\theta)|X\rangle + e^{i\alpha} \sin(\theta)|X'\rangle$ and $|\psi\rangle = \cos(\theta')|Y\rangle + e^{i\beta} \sin(\theta')|Y'\rangle$ with $\alpha, \beta \in \mathbb{R}$. Then we have
\[||DC|\psi\rangle||^2 = \cos^2(\theta) ||D|X\rangle||^2 \geq \cos^2(\theta) ||Y|X\rangle||^2 \geq \cos^2(\theta) \cos^2(\theta + \theta').\]

We now prove Lemma 1.

**Proof.** Let $|\Omega\rangle_{AB}$ be the joint pure state shared by Alice and Bob, where $A$ is the space controlled by Alice and $B$ the space controlled by Bob.

Let $M = \{M_{x_0,x_1}\}_{x_0,x_1 \in \{0,1\}}$ be Alice’s projective measurement on $A$ to determine her outputs $x_0, x_1$. Let $P = \{P_0, P_1\}$ be Bob’s projective measurement that allows him to guess $x_0$ with probability $p = \cos^2(\theta)$ and $Q = \{Q_0, Q_1\}$ be Bob’s projective measurement that allows him to guess $x_1$ with probability $q = \cos^2(\theta')$. These measurements are on $B$ only. Recall that $a = \frac{p + 1}{2} = \frac{\cos^2(\theta) + \cos^2(\theta')}{2}$. We consider the following projections on $AB$:
\[C = \sum_{x_0,x_1} M_{x_0,x_1} \otimes P_{x_0} \quad \text{and} \quad D = \sum_{x_0,x_1} M_{x_0,x_1} \otimes Q_{x_1}.\]

$C$ (resp. $D$) is the projection on the subspace where Bob guesses correctly the first bit (resp. the second bit) after applying $P$ (resp. $Q$).

A strategy for Bob to learn both bits is simple: apply the two measurements $P$ and $Q$ one after the other, where the first one is chosen uniformly at random.

The projection on the subspace where Bob guesses $(x_0, x_1)$ when applying $P$ then $Q$ is
\[E = \sum_{x_0,x_1} M_{x_0,x_1} \otimes Q_{x_1} P_{x_0} = DC.\]
Similarly, the projection on the subspace where Bob guesses \((x_0, x_1)\) when applying \(Q\) then \(P\) is

\[
F = \sum_{x_0, x_1} M_{x_0, x_1} \otimes P_{x_0} Q_{x_1} = CD.
\]

With this strategy Bob can guess both bits with probability

\[
\frac{1}{2} \left( ||E|\Omega|_2^2 + ||F|\Omega|_2^2 \right) = \frac{1}{2} \left( ||DC|\Omega|_2^2 + ||CD|\Omega|_2^2 \right) \\
\geq \frac{1}{2} \left( \cos^2(\theta) + \cos^2(\theta') \right) \cos^2(\theta + \theta') \\
\geq \frac{1}{2} \left( \cos^2(\theta) + \cos^2(\theta') \right) (\cos^2(\theta) + \cos^2(\theta') - 1)^2 \\
= a(2a - 1)^2.
\]

Note that we can use Proposition 2 since Bob’s optimal measurement to guess \(x_0\) and \(x_1\) succeeds for each bit with probability at least \(1/2\).

**4 A Two-Message Protocol With Bias 1/4**

We present in this section a random-\(OT\) protocol with bias 1/4. This implies, as we have mentioned, an \(OT\) protocol with inputs with the same bias.

<table>
<thead>
<tr>
<th>Random Oblivious Transfer Protocol</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Bob chooses (b \in_R {0, 1}) and creates the state (</td>
</tr>
<tr>
<td>2. Alice chooses (x_0, x_1 \in_R {0, 1}) and applies the unitary (</td>
</tr>
<tr>
<td>3. Alice returns the qutrit to Bob who now has the state (</td>
</tr>
<tr>
<td>4. Bob performs on the state (</td>
</tr>
<tr>
<td>If the outcome is (\Pi_0) then (x_b = 0), if it is (\Pi_1) then (x_b = 1), otherwise he aborts.</td>
</tr>
</tbody>
</table>

It is clear that Bob can learn \(x_0\) or \(x_1\) perfectly. Moreover, note that if he sends half of the state \(\frac{1}{\sqrt{2}}|00\rangle + \frac{1}{\sqrt{2}}|11\rangle\) then he can also learn \(x_0 \oplus x_1\) perfectly (although in this case he does not learn either of \(x_0\) or \(x_1\)). We now show that it is impossible for him to perfectly learn both \(x_0\) and \(x_1\) and also that his bit is not completely revealed to a cheating Alice.

**Theorem 2.** In the protocol described above, we have \(A_{OT} = B_{OT} = \frac{2}{3}\).

In the full version, we prove this theorem. In the previous section we have shown that no protocol has bias lower than 0.0586 by showing that \(A_{OT} f(B_{OT}) \geq 1/2\). In this section we presented a protocol with bias 0.25 and it can be calculated that for this protocol we have \(A_{OT} f(B_{OT}) = \frac{4}{3} f\left(\frac{4}{3}\right) \approx 0.709\). It remains an open problem to determine the bias of an optimal protocol.
5 Oblivious Transfer as a Forcing Primitive

Here we discuss a variant of oblivious transfer, as a generalization of coin flipping, that can be analyzed using an extension of Kitaev’s semidefinite programming formalism.

**Definition 3 (Forcing Oblivious Transfer).** A $k$-out-of-$n$ forcing oblivious transfer protocol, denoted here as $(n^k)$-fOT, with forcing bias $\varepsilon$ is a protocol satisfying:

- Alice outputs $n$ random bits $x := (x_1, \ldots, x_n)$
- Bob outputs a random index set $b$ of $k$ indices and bit string $x_b$ consisting of $x_i$ for $i \in b$
- $A_{b,x_b} := \sup\{\Pr[\text{Alice can force Bob to output } (b,x_b)]\} = \frac{\varepsilon_A}{\binom{n}{k}} \cdot 2^k$
- $B_x := \sup\{\Pr[\text{Bob can force Alice to output } x]\} = \frac{\varepsilon_B}{2^n}$
- The forcing bias of the protocol is defined as $\varepsilon = \max\{\varepsilon_A, \varepsilon_B\}$

where the suprema are taken over all strategies of Alice and Bob.

The main difference in this new primitive is the definition of security. We design protocols to protect against a dishonest party being able to force a desired value as the output of the other party. In the previous section (and in the literature) oblivious transfer protocols are designed to protect against the dishonest party learning the other party’s output. Notice, for example, that in coin flipping we can design protocols to protect against a dishonest party forcing a desired outcome, but both players learn the coin outcome perfectly.

The primitive we have defined is indeed a generalization of coin flipping since we can cast the problem of coin flipping as a 1-out-of-1 forcing oblivious transfer protocol. Of course, in $(\binom{1}{1})$-fOT Alice always knows Bob’s index set so the forcing bias is the only interesting notion of security in this case.

We define the bias $\varepsilon$ as a multiplicative factor instead of additive since the honest probabilities can be different and in this case our definition makes more sense. To relate this bias to the one previously studied in coin flipping we have that coin flipping protocols with bias $\varepsilon \leq \sqrt{2} + \delta$ exist for any $\delta > 0$, see [CK09], and weak coin flipping protocols with bias $\varepsilon \leq 1 + \delta$ exist for any $\delta > 0$, see [Moc07].

5.1 Extending Kitaev’s Lower Bound to Forcing Oblivious Transfer

We now extend Kitaev’s formalism from the setting of coin flipping to the more general setting of $(\binom{n}{k})$-fOT.

Suppose Alice and Bob have private spaces $\mathcal{A}$ and $\mathcal{B}$, respectively, and both have access to a message space $\mathcal{M}$ each initialized in state $|0\rangle$. Then, we can define an $m$-round $(\binom{n}{k})$-fOT protocol using the following parameters:

- Alice’s unitary operators $U_{A,1}, \ldots, U_{A,m}$ which act on $\mathcal{A} \otimes \mathcal{M}$
- Bob’s unitary operators $U_{B,1}, \ldots, U_{B,m}$ which act on $\mathcal{M} \otimes \mathcal{B}$
- Alice’s POVM $\{\Pi_{A,abort}\} \cup \{\Pi_{A,x} : x \in \mathbb{Z}_n^k\}$ acting on $\mathcal{A}$, one for each outcome
- Bob’s POVM $\{\Pi_{B,abort}\} \cup \{\Pi_{B,(b,x_b)} : b \text{ a } k\text{-element subset of } n \text{ indices, } x_b \in \mathbb{Z}_n^b\}$ acting on $\mathcal{B}$, one for each outcome.

We now show the criteria for which the parameters above yield a proper $(\binom{n}{k})$-fOT protocol. In a proper protocol we require that Alice and Bob’s measurements are consistent and that the outcomes are uniformly random when the protocol is followed honestly. Define

$$|\psi\rangle := (I_A \otimes U_{B,m})(U_{A,m} \otimes I_B) \cdots (I_A \otimes U_{B,1})(U_{A,1} \otimes I_B)|0\rangle_{A \otimes M \otimes B}$$
to be the state at the end of an honest run of the protocol. Then, we require the unitary and measurement operators to satisfy the following condition:

\[ \| (\Pi_{A,x} \otimes I_M \otimes \Pi_{B,(b,x_b)}) |\psi\rangle \|^2 = \frac{1}{(\binom{n}{k})^2} \text{ for } (x, b, x_b) \text{ consistent.} \]

Similar to coin flipping, we can capture cheating strategies as semidefinite programs. Bob can force Alice to output a specific \( x \in \mathbb{Z}_n^2 \) with maximum probability equal to the optimal value of the following semidefinite program

\[
B_x = \max_{\rho} \langle I_M \otimes \Pi_{B,(b,x_b)}, \rho_B,N \rangle \\
\text{subject to} \\
\text{Tr}_M(\rho_{B,0}) = |0\rangle\langle 0|_B \\
\text{Tr}_M(\rho_{B,j}) = \text{Tr}_M(U_{B,j}\rho_{B,j-1}U_{B,j}^*), \text{ for } j \in \{1, \ldots, N\} \\
\rho_{B,0}, \ldots, \rho_{B,N} \in \text{Pos}(B), \text{ for } j \in \{1, \ldots, N\}
\]

where \( \text{Pos}(H) \) is the set of positive semidefinite matrices over the Hilbert space \( H \). The states \( \rho_i \) represent the part of the state under Alice’s control after Bob sends his \( i \)th message. The constraints above are necessary since Bob cannot apply a unitary on \( A \). They are also sufficient since Bob can maintain a purification during the protocol consistent with the states above to achieve a cheating probability given by the corresponding objective value.

To capture Alice’s cheating strategies we can do the same as for cheating Bob and examine the states under Bob’s control during the course of the protocol. That is, Alice can force Bob to output a specific \( k \)-element subset \( b \) and \( x_b \in \mathbb{Z}_k^2 \) with maximum probability equal to the optimal value of the following semidefinite program

\[
A_{b,x_b} = \max_{\rho} \langle I_M \otimes \Pi_{B,(b,x_b)}, \rho_B,N \rangle \\
\text{subject to} \\
\text{Tr}_M(\rho_{B,0}) = |0\rangle\langle 0|_B \\
\text{Tr}_M(\rho_{B,j}) = \text{Tr}_M(U_{B,j}\rho_{B,j-1}U_{B,j}^*), \text{ for } j \in \{1, \ldots, N\} \\
\rho_{B,0}, \ldots, \rho_{B,N} \in \text{Pos}(B), \text{ for } j \in \{1, \ldots, N\}
\]

The proofs that these capture the optimal cheating probabilities are the same as those for coin flipping in [Kit03] and [ABDR04]. Using these semidefinite programs we can prove the following theorem.

**Theorem 3.** In any \( \binom{n}{k} \)-OT protocol and consistent \( b, x, x_b \) we have

\[ B_x \cdot A_{b,x_b} \geq \Pr[\text{Alice honestly outputs } x \text{ and Bob honestly outputs } (b, x_b)] = \frac{1}{(\binom{n}{k})^2}. \]

In particular, the forcing bias satisfies \( \varepsilon \geq \sqrt{2}^k \).

Once we extended the semidefinite programming formulation, the proof of the theorem follows almost directly from the proof in [Kit03] and [ABDR04] for coin flipping except that the honest outcome probabilities are different in our case. Namely, for \( |\psi\rangle \) defined above, we have

\[ \| (\Pi_{A,x} \otimes I_M \otimes \Pi_{B,(b,x_b)}) |\psi\rangle \|^2 = \frac{1}{(\binom{n}{k})^2} \]

when \( x, b, \) and \( x_b \) are consistent and 0 otherwise.
5.2 A Protocol with Optimal Forcing Bias

In this section we prove Theorem 4. First, consider the following protocol which achieves the bound in Theorem 3 but is asymmetric. Alice sends $n$ random bits to Bob. Bob then outputs $b$, a random $k$-index subset of $n$ indices, and $x_b$. In this protocol Bob can force a desired outcome with probability $\frac{1}{2^n}$ and Alice can force a desired outcome with probability $\frac{1}{\binom{n}{k}}$. Thus the product of the cheating probabilities is optimal, that is it achieves the lower bound in Theorem 3. However the protocol is asymmetric. This can be easily remedied using coin flipping. We present an optimal protocol with this security definition.

An Optimal $\binom{n}{k}$-fOT Protocol with Forcing Bias $\sqrt{2}^k$

1. Bob outputs a random index set $b$ of $k$ indices and sends the result to Alice.
2. Alice and Bob play a coin flipping game with bias $\sqrt{2} + \delta$ (for a $\delta > 0$ sufficiently small) to determine each bit in $x_b$.
3. Alice randomly chooses her bits not in $b$.

**Theorem 4.** For any $\gamma > 0$ we can choose a $\delta > 0$ such that the $\binom{n}{k}$-fOT protocol above satisfies

$$A_{b,x_b} \leq \frac{\sqrt{2}^k (1 + \gamma)}{\binom{n}{k} \cdot 2^k} \quad \text{and} \quad B_x \leq \frac{\sqrt{2}^k (1 + \gamma)}{2^n}.$$ 

We prove this theorem in the final version. Note that we have coin flipping protocols with $\text{poly}(m)$ rounds that achieve $\delta = \frac{1}{\text{poly}(m)}$. Hence, our protocol also achieves $\gamma = \frac{1}{\text{poly}(m)}$ with $\text{poly}(m)$ rounds.
